CHARLES JOHNSON

REAR ADMIRAL

UNITED STATES NAVY

NEW YORK

BY WILLIAM A. FINE

PREFACE

TO THE

EIGHTH EDITION.

THE last edition of COOPER'S SURGICAL DICTIONARY appeared under the auspices of its laborious and talented author, who devoted, with unprecedented ardour, a whole life to the production and perfection of his favourite work. His great abilities and untiring energy enabled him, in seven successive editions, spread over a period of nine-and-twenty years, to present to the world an epitome of surgical science unrivalled, as the production of one man, for its accuracy, for its great research, and for the amount of information it has been the means of accumulating and disseminating for the last half century, amongst surgeons in this country, and throughout the civilised world. In the preface to his seventh and last edition, Mr. Cooper thus writes of himself and his labours:—

“The utility of this Dictionary to students and all classes of medical practitioners, has obtained for it in this country a larger share of patronage than perhaps was ever conferred upon any other book of Surgery; while its translation into the French, German, and Italian languages, and several republications of it in America, may be taken as proofs of its being deemed worthy of considerable notice in various parts of the world.”

“In preparing this edition, which comprehends an account of all the principal modern improvements in Surgery, I have conscientiously endeavoured to deal fairly and impartially with every individual whose name I have had occasion to mention, or whose suggestions form subjects of consideration, in the ensuing pages. My aim has been Truth, wherever I could find her; and in every situation where any glimpse of her beautiful figure presented itself, I have ardently courted her, regardless of the name, school, or country on which she might deign to shed her glory. By steadily adhering to this principle; by zealously marking what the book of nature and the field of experience unfolded; by renouncing all obsequious submission to every other kind of authority; and by taking the liberty of sometimes thinking and judging for myself; I trust that the most likely plan has been adopted of maintaining the character of this book, and raising my own reputation.”

Mr. Cooper adds the following quotation from the preface of Dr. Reese's American edition of the Dictionary:—

“As in every species of human science, our highest attainments are but an approximation towards perfection; so in the science of Surgery, each succeeding year demonstrates that all that is known of the principles or practice of our art, is but the prelude to still higher exhibitions of science and skill, alike honourable to the profession, and valuable to the cause of humanity. To condense and arrange all the novel and interesting facts which clinical experience is furnishing, and upon which alone the edifice of true science can be erected, is a task worthy of the immense labour which Mr. Cooper has bestowed on each succeeding reprint of his Dictionary, and one to which he has proved himself entirely adequate. The extensive and multiplied resources to which he has access, furnish him with facilities possessed by few; and in availing himself of these, he has exhibited an industry, and, for the most part, an impartiality, worthy of all praise.”

The task that has devolved upon the present Editor is to embody in the Eighth Edition of the work thus characterised by its illustrious author, all that has been subsequently achieved in the art and science of Surgery. Since the names of Liebig, Mulder, Robin, and Verdeil have appeared amongst us, chemistry, especially animal chemistry, has not only made rapid strides, but, as regards its influence on the study of morbid products of either a solid or fluid nature, may be considered almost a new science. The microscope, in the hands of Schwann and Schleiden, has led to the discovery of cell development, unveiling to us the important part played by the nucleated cell in the vital functions of secretion and excretion, and the further knowledge that the blood itself is composed of nucleated cells, movable in the liquor sanguinis, and conveyed by the circulation to every organ and tissue in the body. The vast improvements in histological and pathological anatomy, introduced by Rokitsansky, Paget, and Virchow, have entirely altered our notions of healthy and morbid growths. The discovery of the laws of endosmosis and exosmosis, by Dutrochet, added to our improved knowledge of the peripheral terminations of the whole vascular system, have led to the subversion of the Hunterian doctrine of absorption and deposition by the open mouths of the absorbents and arteries. The gradual introduction of humoral pathology, and the equally gradual extinction of pure solidism; and lastly, the new views in the treatment of inflammatory diseases by stimulants, as advocated by the late Dr. Todd and others, perhaps too readily received and adopted by many of the rising generation of medical men, to the exclusion of the heroic remedies of repeated bleedings and salivations, — hitherto too zealously and too indiscriminately had recourse to, — have all had a powerful influence in modifying the opinions held by surgeons of the present day with regard to the nature and treatment of most surgical diseases.

The necessity that these new lights should be made to pervade more or less the pages of this dictionary, and that the prolific and teeming professional literature of the last quarter of a century should be consulted on every branch of Surgery, rendered it physically impossible that the Editor should himself revise each separate article. He has accordingly associated with him in his editorial labours many eminent and able writers, for the most part already distinguished in the de-

partment of Surgery which they have undertaken, as will be at once recognised in the following list of subjects and contributors:—

MR. J. ADAMS . . .	Head, Injuries of.
MR. W. ADAMS . . .	Orthopædic Surgery.
MR. ANCELL . . .	Articles on Blood; Tuberculosis.
DR. BADER . . .	Ophthalmic Surgery.
MR. BUSK . . .	Scurvy.
MR. BLENKINS . . .	Gun-shot Wounds.
MR. WHITE COOPER .	Cataract.
MR. COULSON . . .	Lithotomy and Lithotrity.
MR. DRUITT . . .	Inflammation and its Terminations.
MR. ERICHSEN . . .	Aneurism
MR. FERGUSSON . . .	Staphyloraphe.
DR. HANFIELD JONES	Cancer and Malignant Diseases.
MR. E. HART . . .	Hydrophobia; Tetanus.
MR. J. R. LANE . . .	Amputation; Fractures and Dislocations; Diseases of the Rectum.
DR. MCLEOD . . .	Varix.
MR. SPENCER SMITH .	Bones, Diseases of.
DR. SNOW . . .	Anæsthesia.
DR. TYLER SMITH . .	Articles on Obstetric Surgery.
MR. H. THOMPSON . .	Urethral and Prostatic Diseases.
MR. THOS. WAKLEY .	Joints, Excision of; Joints, Diseases of; Hydrocele, &c.
MR. SPENCER WELLS .	Plastic Surgery; Burns, &c.
MR. ERASMUS WILSON	Skin, Diseases of.
MR. URE . . .	Caustics; Mamma, Diseases of.

The pathology of the blood will be found a very important addition which has contributed to augment the pages of the work. This subject in its entirety has been undertaken by Mr. Ansell, whose competency to the task is well established by the publication in the year 1841-42 of his "Lectures on the Physiology and Pathology of the Blood," which with the contemporaneous writings of Andral, Stevens, Piorry, Copland, and others, unquestionably influenced the progress of Medical and Surgical Science and the direction it subsequently took. At the period of the publication of the last edition, but slight account had been taken by surgeons of the blood as a vital constituent of the animal frame, or the seat of either the material elements, or the dynamic actions which enter into morbid processes. But at the present day, in every department of surgical practice, the question of the actual state of the blood must be entertained before any case can be fully compassed or rational indications of treatment, whether by operation or otherwise, can be laid down. Under these circumstances, the duty of the editor would appear to be to present to the surgical practitioner and the student a fair summary of all that is known on the subject. The accomplishment of this has been attempted in the Articles—*Blood, Pathology of*—*Cholæmia*—*Hydræmia*—*Hyperinosis*—*Hypinosis*—*Heterochymeusis*—*Hyperæmia*—*Oxalæmia*—*Necræmia*—*Pyæmia*—*Toxæmia*—*Spanæmia*, *Uræmia*, &c. Some of the articles have been through the press for a considerable period, but the writer has contrived so to arrange the materials that, under the various headings above specified, will be found comprised a sufficiently complete view of the actual state of our knowledge of the pathology of the blood.

The plan adopted in conducting the present edition through the press has been, to retain as much as possible of the original matter,

whether historical or strictly professional; to erase only that which by lapse of time had become obsolete, or which the accumulated experience and the advance of the collateral sciences had shown to be at variance with the improved knowledge of the day. The addition of new matter has been restricted, as much as possible, to the space rendered available by the erasures, in order to keep the work within the compass of a dictionary of convenient reference. In many instances this has not been found possible, and a considerable extension of certain articles has been unavoidable. A few have been entirely re-written. New ones have also of necessity been added. Orthopædic surgery—Ovariectomy—Excision of Joints—the treatment of Vesicovaginal Fistula and of Ruptured Perinæum, &c.—have assumed the position of new branches of Surgery since the last edition of this Dictionary, and have consequently demanded much additional space. The result has been, that with every desire and every effort to exceed as little as possible the bulk of the last edition, the present—notwithstanding the space gained by the numerous erasures, which have been unsparingly had recourse to—will contain at least 500 additional pages of new matter.

The reader will at once understand who is responsible for the revision or authorship of any article by observing the presence or absence of a name at the end of the article. In the latter instance the Editor himself is answerable; in the former the writer whose name is attached. Throughout the work the new matter is distinguished from the original of Mr. Cooper by being enclosed in brackets; that which has been erased could not be indicated.

The unavoidable increase in bulk of the present edition has induced the Publishers to divide the work into two volumes. The First is now presented to the professional public. The Editor, however imperfectly he may have thus far performed his task, has endeavoured, to the best of his abilities, to follow, *haud passibus æquis*, in the footsteps of Mr. Cooper; actuated by similar aspirations for the advancement of our noble and beneficent science, his aim has been to carry out the declared intentions of the author with the same independence of thought, the same devotion to truth wherever found, and to adopt the same spirit of fairness and impartiality in recording the discoveries and opinions of cotemporary surgeons.

To the Second Volume, which will appear as speedily as possible, will be added an Appendix, in which will be embodied the latest discoveries and improvements. This plan, which was adopted in former editions by the late author, is rendered absolutely necessary—especially as regards the articles belonging to the earlier letters of the Alphabet—by the rapid progress of Surgical Science, and by the long period unavoidably occupied by a work of this magnitude in passing through the press.

A

DICTIONARY

OF

PRACTICAL SURGERY.

ABD

ABDOMEN. The **BELLY.** If the pelvis be reckoned as part of the abdomen, the latter may be said to extend from the diaphragm, which forms its upper boundary, down to the levatores ani, and, from the transversales muscles in front, to the spine, quadrati lumborum, and iliaci behind. Thus comprehensively viewed, the abdomen appears to contain and protect all the organs of digestion situated below the œsophagus, together with the urinary and internal organs of generation. Anatomists divide the abdomen into different *regions*, the terms allotted to which are so frequent in the language of surgery, that some account of them in this Dictionary seems indispensable. In fact, without the knowledge of them, the pathologist can neither direct his inquiries with precision, nor communicate clearly the results of his investigations to others. The abdomen has been divided into as many as nine compartments or regions, by four lines drawn arbitrarily between certain points, readily distinguishable on the surface, two of these lines are imagined to pass on either side from the cartilage of the eighth rib down to the centre of Poupart's ligament,—thus dividing the anterior surface of the abdominal paries into three longitudinal compartments, a central and two lateral. Each of these is again subdivided into three others by two lines extended transversely, the one between the lowest level of the costal cartilages, the other between the highest level of the iliac crests of opposite sides, cutting the former perpendicular lines at right angles. Partitions corresponding with these four lines are supposed to pass through the abdomen from its anterior to its posterior boundary, marking out the positions of the nine conventional compartments or regions into which the abdominal cavity is supposed to be divided. Enumerating from above downwards the three central of these regions are named the Epigastric, the Umbilical, and the Hypogastric; the lateral are termed the Hypochondriac, the Lumbar, and the Iliac. The *epigastric region* contains the middle part and the pyloric extremity of the stomach, the left lobe of the liver, the hepatic vessels, the lobulus spigelii, the pancreas, the cœliac axis, the semilunar ganglia, the aorta, the vena cava, and the crura of the diaphragm. The *left hypochondrium* contains the large end of the stomach, the spleen and narrow extremity of the

ABD

pancreas, part of the colon, the renal capsule, and the upper portion of the kidney. The *right hypochondrium* contains the right lobe of the liver, the gall-bladder, part of the duodenum, some of the ascending colon, the renal capsule, and upper portion of the kidney. In the umbilical region are situated the transverse colon, the transverse portion of the duodenum, the aorta, the vena cava, and the convolutions of the jejunum. The *right lumbar region* contains the ascending colon, the lower half of the kidney, and part of the duodenum. The *left* contains the descending colon, and the lower half the kidney. In the *hypogastric region* are the convolutions of the ilium, the bladder in children, and, in adults, both the bladder and the uterus, if distended. The *right iliac* contains the cœcum, the ureter, and spermatic vessels, and the *left iliac*, the sigmoid flexure of the colon, the ureter, and the spermatic vessels.

Although the upper boundaries of the abdomen are completely determined internally by the diaphragm, they remain quite undefined externally. The diaphragm being a movable partition between the chest and the abdomen, alternately ascending and descending in respiration, must by such changes have the effect of occasioning a correspondent enlargement or diminution of one of these cavities at the expense of the other. Without attention to this fact, mistakes in diagnosis would be very frequent. A sword, entering at the same point, and in the same direction, may penetrate the thorax, or the abdomen, or both cavities, according to the position of the diaphragm at the moment of the injury.

The functions of the abdomen essentially require that its capacity should be continually varying; and had its cavity been circumscribed by an osseous case, like that of the cranium, or by a construction like that of the parietes of the chest, such an arrangement would have been totally incompatible with the offices of the abdominal viscera. So convinced is Cruveilhier of the facility with which the abdomen accommodates itself to the varying quantity of its contents, that he regards the doctrine as perfectly erroneous which refers the irreducible state of some herniæ to insufficiency of space within the peritoneum. "What!" says he, "can we suppose a cavity incapable of receiving the bowels again, which will allow of

eight or ten pounds of victuals and drink being suddenly introduced into it? and which, in tympanitis, often becomes distended in a short time to twice or thrice its natural dimensions?" According to the judgment of this distinguished pathologist, the obstacle to reduction depends either upon adhesions, or a disproportion between the viscera and the passage through which they protrude, arising from hypertrophy of the omentum, or mesentery; or the altered relations of the peritoneum, drawn down by the displaced intestines. But though this explanation, so far as it goes, seems correct with reference to the causes of the impossibility of reduction, Cruveilhier's view should not lead us to forget, that certain cases every now and then present themselves where the viscera admit of reduction; but their return into the abdomen is followed by so much pain and indisposition, that the plan of keeping them there is unavoidably renounced.

In the treatment of several diseases and injuries of the abdomen, the surgeon cannot proceed one step with safety to his patient without the light of anatomy. Hernia, wounds, paracentesis, abscesses, are all so many cases where a surgeon deficient in anatomical knowledge would be likely to adopt very inefficient measures, or commit the most fatal mistakes. A surgeon, acquainted with the structure and extent of the sheath of the rectus, would have no difficulty in selecting the most advantageous place for the puncture, when matter collects within that investment of the muscle; and the practitioner, aware of the exact course of the epigastric artery, would never run any risk of wounding it either in tapping a dropsical patient, attempting to take up the external iliac artery, or dividing the stricture in inguinal and crural herniæ.

On being first consulted, surgeons, as well as physicians, too often neglect to institute a careful examination of the external parts of the body. Thus, either from carelessness or mistaken delicacy, they deprive themselves of the most simple, ready, and sure means of recognising the nature of the patient's complaint. Some diseases of the chest and abdomen are strikingly expressed on the surface; either in a permanent change of configuration, or in a temporary alteration of the natural movements, or both. (*Forbes, in Cyclop. of Pract. Med. art. Abdomen, Exploration of.*) When obstinate constipation, great pain, nausea, and vomiting occur, let the surgeon always be sure that these symptoms are not dependent upon hernia, the usual situations of which should be carefully explored. The methods of exploring the abdominal regions are three, viz. *inspection*, *manual examination*, or *palpation*, as it is termed, and *percussion*. The assistance of the sight and touch alone is not what the practitioner should always be content with; for as there is more or less gas within the alimentary canal, and considerable arterial trunks pervade the abdomen, the sense of hearing may be exerted with as much success in the investigation of diseases of this part of the body, as in that of diseases of the chest. The parietes of the abdomen being capable of relaxation, the viscera may be felt directly through them; and, as Cruveilhier justly remarks, this is the only visceral cavity admitting of such exploration. Frequently, by means of palpation, tender, enlarged, or indurated points may be de-

tected. In the first instance, however, a careful inspection of the surface of the abdomen should always be made. The practitioner should consider whether it is more bulky, or of less size, than natural. Swelling and tension, combined with pain, and a small frequent pulse, characterise acute peritonitis. In some cases, a circumscribed swelling points out the seat of the disease,—the organ affected. How essential the knowledge of the various regions of the abdomen, and of the contents of each of them, will be for the formation of a correct opinion, must be sufficiently manifest. In pregnancy, retention of urine, and encysted dropsy, the swelling has an oval, or protuberant form; in ascites, a broader, more expanded shape. In lead colic, the parietes of the abdomen seem retracted, or drawn inwards. When palpation is instituted, the abdominal muscles should be relaxed, and the patient's mind diverted from his case. The pressure should be made gently and gradually; for when it is too forcible and abrupt, the examiner's touch is confused, the patient is put to pain, and his muscles contract. According to Cruveilhier, it has even been known to occasion the death of children by lacerating the liver, or the spleen in a state of enlargement. In fact, this rude mode of palpation conveys to the surgeon no information which can be relied upon; for the uneasiness, or pain experienced, or the change of countenance, may be more owing to the roughness or force of the pressure than to any disease in the region of the abdomen subjected to examination. In certain cases, like ascites, the exploration should be made, if possible, while the patient is standing up, because, in this position, the fluid gravitates and renders the parietes of the abdomen tense, so that the fluid is more plainly distinguished.

The presence of gas, or liquids, may be detected by percussion; that of liquids, or any foreign body, being made manifest by the dull dead sound, and the perception of fluctuation by the hand applied to the point opposite that which receives the percussion.

In diseases and injuries of the abdomen, the diagnosis is often attended with considerable obscurity. It might be supposed, that as the soft and yielding parietes of this cavity facilitate the manual examination of its viscera, the detection of any painful point about them, and the slightest change of their shape or volume, nothing would be more easy than to trace disease in this part of the body through its different stages with great precision. But, as Cruveilhier remarks, this is far from being the fact. The vast number of organs contained in the abdomen, their great moveableness, the frequency of their displacement, the multitude of their diseases, the particular character of their vitality, which sometimes lets them attain a very serious state of disease, unattended by any urgent pain; and lastly, the difference of thickness of the parietes of the abdomen in different individuals, are undoubtedly the circumstances accounting for the frequent difficulty in the diagnosis. In surgical, as well as in medical cases, the same uncertainty is experienced. Thus punctured wounds of the abdomen are treated on general principles, because the practitioner seldom knows exactly what viscera are injured. The same observation is applicable to contusions of the abdomen. A man who had a hernia received the

kick of a mule on the belly : severe colic and vomiting ensued ; several surgeons believed that these symptoms arose from the hernia being strangulated, and recommended an operation. Cruveilhier objected to this proposal, which, however, was carried into execution: the patient died, and on opening the body, the small intestine was found torn completely across. In the North London Hospital a young man died this spring (1836), from the kick of a horse on the abdomen. During the four or five days which he lived after the accident, he frequently vomited, and the belly became considerably swollen. Effusion of blood, or of the intestinal contents, was foretold ; but, until the *post mortem* examination took place, the exact nature of the injury remained doubtful. A laceration of the small intestine was then detected, attended with effusion of its contents. The man died of peritoneal inflammation.

Abdomen, Abscesses of the, may take place either in its cavity or its parietes, and may be acute or chronic. In fatal examples of peritonitis, a sero-purulent fluid is often found in the cavity of the abdomen. In some instances, the pus is circumscribed by adhesions, which are produced by coagulable lymph, and separate the abscess from the rest of the general cavity of the peritoneum. In other cases purulent effusion in the abdomen is the consequence of the bursting of an abscess of some of the viscera, or of perforation of the small intestine by ulceration.

Chronic tumours of the mesentery, which, in scrofulous children, sometimes terminate in suppuration, diseases of the ovary, and other abdominal viscera, bringing on the formation of matter, may be followed by purulent extravasation. Dr. Seymour in his work on *Diseases of the Ovaries*, relates the case of a young woman, who, after suffering hectic fever, the cause of which was not apparent, suddenly complained of acute pain in the abdomen, and in a few hours expired. On opening the body, a large quantity of pus was found effused in the peritoneal cavity from an abscess of the right ovary. Dr. Tweedie met with an ovarian abscess of the size of an orange, where the prominent symptoms were incontrollable vomiting and sympathetic fever. (*Cyclop. of Pract. Med.* art. *Abscess*.) I have seen several instances of ovarian cysts, which had become inflamed after tapping, and secreted a puriform fluid. A woman had an ovarial tumour, supposed to be an ovarian dropsy. After death, the cyst was found to contain twenty pints of well-formed pus. (*North Amer. Med. Journ.* 1826.)

Occasionally, however, salutary adhesions are produced between the viscera, and ulceration taking place, an outlet is obtained for the matter through the bladder, anus, or vagina. Thus in the case of a woman, who had had for a long while pains in the right lumbar region, supposed to proceed from suppuration of the kidney, because pus was voided with the urine, the right kidney was found after death in the natural state ; but there was an abscess in the right ovary, which was adherent to the bladder, into which the pus had passed through an ulcerated communication. In another patient, who had voided pus by the anus, the right kidney supplicated, and became adherent to the colon, with which it communicated by a preternatural aperture. For many years, a woman had a hard tumour of considerable size in the abdomen : at length, the

pain of it became intolerable ; and just at the moment when her death was apprehended, an immense quantity of pus was suddenly discharged from the vagina. The pain abated ; the swelling of the belly subsided ; merely the remains of the induration were now perceptible ; and the woman's health was perfectly re-established. (See *Lassus, Pathologie Chir.* t. i. p. 133.)

In one case, an abscess communicated with the cœcum, to which and the parietes of the abdomen, the omentum had become firmly adherent. In this manner, a circumscribed cavity was formed, containing ill-conditioned pus, and three or four seeds of fruit, covered by earthy incrustation. (*Abercrombie on Dis. of the Stomach, &c.* p. 338.)

Abscesses of the liver are more common in hot than temperate climates. Frequently, the liver becomes adherent to the neighbouring parts, and then the matter may be discharged through the parietes of the abdomen, or into the colon, stomach, duodenum, or gall-bladder ; from which latter the pus may descend by the biliary duct into the bowels, and be discharged *per anum*, an instance of which is recorded by Malpighi. Abscesses of the liver have been known to make their way through the diaphragm into the pleura, or into the air cells of the lungs, so that the pus was coughed up. Andral refers to one case, where an abscess of the liver communicated with the vena cava, and to another, where it burst into the pericardium. (*Anat. Pathol.* t. ii. p. 601.) At the request of the late Dr. Pinckard, I examined the body of a woman, in whose liver there were nearly three pints of pus ; the case was remarkable on account of the gall-bladder having been annihilated, with the exception of a trivial portion of its fundus, which is now in my possession.

The kidney may be the seat of acute or chronic abscess. Sometimes the quantity of matter is small, and the texture of the organ but little changed. In other examples, the suppuration may be so copious that none of the original structure of the kidney is left, excepting its capsular investment, which is expanded into a cyst of considerable size, and filled with pus. I attended with Mr. Baker, of Staines, an old man who had symptoms somewhat like those of stone, and one of whose kidneys was found after death converted into a cyst containing about a pint of purulent fluid. As Andral observes, renal abscesses are sometimes so large, that they may be felt through the parietes of the abdomen. (*Anat. Pathol.* t. ii. p. 633.)

Abscesses of the kidney may burst in the loins, or make their way into the peritoneum, the ureter, or the colon.

Abscesses between the peritoneum and abdominal muscles, or between the layers of these muscles, or under the integuments of the abdomen, are attended with considerable variety, according as they happen to be chronic, or acute ; circumscribed, or diffused ; small, or extensive. Those of the acute or phlegmonous kind, from stabs and contusions, are noticed in the article WOUNDS. As for chronic abscesses of the parietes of the abdomen, they should be opened in an early stage.

Hard indigestible substances, after being swallowed, are not unfrequently discharged from abscesses in some of the abdominal regions. (See *De La Grange, in Museum der Heilkunde*, b. iv. p. 154 : *a fish-bone, which had been swallowed*,

found in the abscess; *Petit, Traité de Mal. Chir.* t. ii. p. 226; an awl, without a handle, extracted from an abscess of the abdomen; and many other analogous cases.)

Encysted tumours are occasionally formed between the peritoneum and abdominal muscles, and attain an immense size before they burst; a remarkable specimen of which is described by Gooch, (*Chir. Works*, vol. ii. p. 144, &c. 8vo. Lond. 1792.) In this case, the spontaneous opening in the navel was enlarged with caustic, and the cyst extracted; but, before a cure could be effected, it became necessary to make a depending opening, and introduce a seton.

Abdomen, Pulsations in the.—From the article *Aneurism*, the reader will understand that, though it be the common nature of this disease to be attended with throbbing, it is not every pulsating tumour that is an aneurism. The cases, usually called *abdominal* or *epigastric pulsations*, often furnish a proof of the correctness of the preceding remark. The authors, who have treated of the latter affection with the greatest discrimination, are Dr. Albers, of Bremen, and Mr. Allan Burns, of Glasgow, two gentlemen, whose high reputation and useful labours will long survive the termination of their meritorious lives. Some of the pulsations here referred to are the consequence of organic disease, and capable of demonstration by dissection; while the rest are not attended with any such appearance, and have therefore been regarded as nervous. The pulsation is not always produced by the impulse communicated to a solid tumour, or substance between the hand and the artery, but was conceived by Mr. Burns to be sometimes dependent on a nervous affection of the vessel itself. (*On Diseases of the Heart*, p. 263.) Hippocrates refers to three patients affected with extraordinary pulsations in the abdomen. As one of these cases seemed to depend upon obstructed menses, it was probably not the result of any organic disease. (*Hippocratis Opera Omnia. ex edit. Fæsi Francof.* 1621, lib. v. sect. 7, p. 1144.) In order to remove a difficulty in believing how an artery, not affected with aneurismal enlargement, can communicate to the superincumbent parts such movements as are frequently remarked in cases of abdominal pulsations, a fact pointed out by Mr. Hunter should be remembered: in speaking of the actual dilatation of an artery, he says, that when the vessel is “covered by the integuments, the apparent effect is much greater than it really is in the artery itself; for, in laying such an artery bare, the nearer we come to it, the less visible is its pulsation: and when laid bare, its motion is hardly either to be felt or seen.” (*On the Blood*, &c. p. 175, 4to. Lond. 1794.) And this observation will apply to all tumours and indurations situated over a large artery. In the epigastric region of a certain patient, Taberranus felt not only a pulsation, but a tumour as large as the fist, with all the other usual symptoms of an aneurism. On opening the body after death, he was therefore surprised to find, instead of this disease, a considerable scirrhus tumour in the middle of the mesentery, so closely connected to the large vessels as to compress the aorta, by the pulsations of which it had been lifted up. (*Obs. Anat.* ed. 2, No. 9.)

Mr. Loudon, of Leamington, sent me the particulars of a case, where the pulsations of the aorta

against a diseased liver, extending across the epigastrium, and occasioning a well-defined tumour at the pit of the stomach, had been mistaken by several practitioners for an aneurism of the aorta, which vessel was found after death perfectly sound.

I once visited with Mr. Miller, of Keppell Street, a thin old man for retention of urine, where the tumour, formed by distended bladder above the pubes, was attended with regular and strong pulsations, corresponding to those of the arteries. I am not aware that any similar case is upon record.

In an example recorded by Störk, the symptoms arose from disease of the pancreas, which weighed thirteen pounds, and contained a large cyst filled with lamellated blood. (*Annus Medicus*, Vindob. 1760, p. 245.)

A man, aged 60, complained of pain in the left side, midway between the umbilicus and crista of the ilium, followed by emaciation, weakness, distress of countenance, anorexia, and constipation. At length, a large pulsating tumour was discovered in the epigastric region. The case was now pronounced aneurism of the abdominal aorta. There was *no nausea nor vomiting*, except a few days before death, when a quantity of fetid blackish fluid was twice or thrice voided. *No fever*. The swelling caused a sense of constriction rather than pain, and the throbbing became more perceptible. The pulse was feeble, but *slow and regular*. After death, the stomach was found *adhering* to the liver, pancreas, and peritoneum; and a *cancerous tumour* occupied its internal surface from the duodenum to the insertion of the œsophagus, its coats being an inch thick. The surface of the pancreas was also diseased, and the pylorus, situated in the midst of the cancerous mass, was contracted by the thickening of the parietes of the stomach, and obstructed by numerous fungi. The liver was large, but apparently sound; the spleen small. *The aorta, the celiac trunk, and its branches were quite natural.* (See *Journ. de Méd. par Leroux*, Oct. 1815.)

Abdominal pulsations are described by Zuliani, as a symptom of hypochondriasis and hysteria. (*De Apoplexia*, Lips. 1790, p. 79.) They also happen in certain febrile diseases. (*Versuch über den Pemphygus und das Blaienfieber, von C. G. C. Braune.* Leipz. 1795, s. 23; and *Dr. R. Jackson on the Fevers of Jamaica*, 8vo. Lond. 1791.)

Thilenius observed a flatulence of the stomach, which, in some patients, was attended with pulsations at the scrobiculus cordis. (*Med. Chir. Bemerk.* Frankf. 1789, s. 211—217.) My friend, Mr. Hodgson, in speaking of pulsations in the epigastrium, which are not the consequence of organic disease, and occur in irritable hypochondriac subjects, states his opinion, that, in some instances, these pulsations are a consequence of distension of the stomach with air, which is thrown against the abdominal muscles by the pulsation of the great blood vessels: and in such cases, the throbbing is diminished by the eructations. (*On the Diseases of Arteries and Veins*, p. 96.)

Dr. Albers detailed some cases which fell under his own notice. A young woman, whose menses were upon her, and who had been for some days constipated, was seized with frequent fainting fits and febrile symptoms, occasionally voiding from the bowels a quantity of dark matter, each evacuation of which was followed by a swoon. One morning

at five o'clock Dr. Albers was sent for, as it was feared the patient was about to die. She was extremely exhausted, and the fainting fits followed each other with hardly any intervals. She could just say, "I feel a throbbing in the belly;" and when Dr. Albers applied his hand to the part, he felt a violent pulsation, extending from the ensiform cartilage down to about the bifurcation of the aorta. The action of the heart was weaker than natural; the pulse at the wrist very small, but not quicker than it had been on the preceding day, and not synchronous with the throbbing in the abdomen. Dr. Albers confesses that, at first, he took the case for an aneurism. Dr. Meyerhoff was of the same opinion. Another physician, however, Dr. Weinholt, entertained doubts of the complaint being aneurismal, saying, that he recollected having read similar cases in Morgagni. These gentlemen decided to persevere in the employment of opening medicines and clysters, combining opium with the former. Under this plan, the pulsations in the abdomen and tightness of the chest diminished in a few days. The stools were at first of the colour of chocolate, but afterwards resumed their natural appearance. The throbings, in a weakened form, however, were perceptible for six weeks longer. The patient at length got quite well, and was remaining so four years afterwards.

A man, about 40, severely afflicted with hypochondriasis, great oppression of the chest, constipation, and tension of the abdomen, tendency to fainting, &c., complained to Dr. Albers that he felt as if his heart had fallen down into his belly, where he was annoyed with an incessant throbbing. Indeed, when Dr. Albers examined the abdominal parietes, he could feel a very strong pulsation, and what is curious, could trace it not only along the track of the aorta, but in the course of the left iliac artery. The pulse at the wrist, which was small, frequent, and hard, did not correspond with the abdominal pulsations. For several days, the evacuations from the bowels had been as black as pitch. After the employment of gentle purgatives all the complaints quickly abated, though the throbings were feebly perceptible for nine months afterwards.

In any persons not very fat, and lying upon their backs, the pulse of the aorta can easily be felt, if strong pressure be made a little to the left of the median line, about half way between the navel and scrobiculus cordis. In certain instances, the pulsation is painfully felt by the patient himself. In many cases of this kind, particularly in nervous individuals, the sense of pulsation is merely the effect of preternatural action of the heart; while, in other examples, it is the effect of the pressure of some hard substance upon the descending aorta, determining a disproportionate quantity of blood to the head, "and giving to the hand placed on the abdomen, and sometimes even to the eye, the appearance of a beating so near the surface, as to lead inexperienced observers to conclude that the aorta is morbidly dilated." According to Dr. Parry, the most common causes are collections of fæces in the colon, requiring repeated and active purgatives, which must bring away almost incredible discharges of stercoraceous matter before the aortal pulsation subsides. (See *Parry's Elements of Pathology &c.*; and the *Medico-Chir. Journ. and Review*, vol. i. p. 157.)

I once attended, with the late Mr. Ramsden, a

boy in Christ's Hospital, who had a considerable abscess in the lumbar region, attended with distinct and forcible pulsations, corresponding to those of the aorta.

Three or four years ago, I was also consulted by Mr. Gilbertson, of Egham, in a case where an enormous abscess in the epigastric region was accompanied by pulsations as strong and synchronous with those of the heart as the throbings of an aortic aneurism.

According to Mr. Allan Burns, a beating is generally felt about the pit of the stomach, in the advanced stage of chronic inflammation of the heart: in this case, when the pericardium is closely adherent to the latter organ, it is corrugated at every contraction of the ventricles, and the diaphragm and liver are elevated. The ventricle, however, having completely emptied itself, is again distended, and, in proportion to the degree of dilatation, the liver and diaphragm descend, whereby an impulse is communicated in the epigastric region. (*On Diseases of the Heart*, p. 263.) This valuable writer cites the remark of Morgagni (Epist. 17, art. 28), that sometimes in hypertrophy of the heart, this organ descends so far as to push the diaphragm into the hypochondrium, and pulsate in that situation, so that the disease is mistaken for an aneurism of the celiac artery. In Mr. Burns' work a memorable case of this description is related. An erroneous judgment is the more likely to be formed in such examples, because the pulsations of the heart and tumour are not exactly simultaneous; for it is not the heart which is felt directly beating, but the liver, which, by the action of the heart, is thrown forwards. Hence the palpable interval between the stroke of the heart and the movement of the liver.

Preternatural pulsation about the epigastrium is stated by Mr. A. Burns to be sometimes occasioned by encysted tumours, attached either to the lower surface of the diaphragm, or formed between the layers of the pericardium towards the diaphragm, as happened in an instance recorded by Lancisi.

Another cause specified by Mr. A. Burns, is enlargement of the vena cava, or of the right auricle of the heart. Senac describes a case, in which the vena cava was as large as the arm, and there had been a violent pulsation in the epigastrium.

The next cause, enumerated by the same gentleman, is increased solidity of the lungs, more especially of their lower acute margins, where they overlap the pericardium. In this case, the pulsation is about the scrobiculus cordis.

Mr. A. Burns notices several other causes of epigastric or abdominal pulsations, already spoken of in the foregoing part of this article, indurations of the pancreas, scirrhus of the pylorus, tumours in the mesentery, or any solid increase of substance about the abdominal aorta, or its principal branches; and, lastly, a peculiar affection of the vascular system itself.

The following observations by Dr. Albers on the criteria between various abdominal pulsations and those of aneurism, appear interesting:—An internal aneurism originates gradually, and the pulsations increase in strength by degrees. Other abdominal pulsations, on the contrary, begin suddenly, and are most violent in the beginning, abating after they have lasted some time.

In an aneurism, the pulsation is synchronous with the stroke of the artery at the wrist; but this is not regularly the case with other pulsations.

Should the patient be affected with melancholia, hypochondriasis, hysteria, or other nervous complaints, void blood from the stomach, or a black matter from the bowels; should there be any hardness or swelling of the abdominal viscera discoverable by the touch, the probability is that the pulsations are not owing to an internal aneurism.

With the exception of cases in which these pulsations are owing to mechanical impediments to the circulation, Dr. Albers believes that they are mostly a symptom of some nervous affection. He also thinks, that the surprise excited by these throbbings arises only from their strength and situation; other analogous, strong pulsations, as, for instance, those of the heart, or of the carotids, being common enough in hypochondriacal and hysterical persons. The same gentleman adverts to the increased action, which, in inflammation, and fevers, is often more conspicuous in some parts of the sanguiferous system than others.

See Ueber Pulsationem im Unterleibe. Bremen, 8vo. 1803. Obs. on some of the most frequent and important Diseases of the Heart; on Aneurism of the Thoracic Aorta; on Preternatural Pulsation in the Epigastric Region, &c. By Allan Burns, p. 262, &c. 8vo. Edinb. 1809.

ABSCESS is derived from the Latin *abscessus*, which signifies a loss or departure, or that something is *gone* (to use a homely English word) from some part of the body; *si quid in aliquâ parte corporis abscesserit*, as Celsus says. The word signifies a collection of pus or puriform fluid, in the substance of any part of the body, or in any of the cavities. Thus we speak of abscess of the areolar tissue, or bone, or brain; and of abscess of the pleura, or joints.

Abscess in the substance of a part is homologous with ulcer on the surface. Each results from the softening down of the natural tissues, and of exudations which have infiltrated them.

There is one question, which commonly is brought forward in discussing the general history of abscess, and that is, whether all abscesses of necessity arise from inflammation. This question will be amply discussed under the article INFLAMMATION; where we shall show that a dispute of this matter is one of words rather than of things. If all exudations are inflammatory, then all abscesses must be so; but until it be settled that the term inflammation shall include all exudation, with hyperæmia, or without it, it will be impossible to deny that abscesses may have no necessary connection with inflammation.

The subject of abscesses admits of a twofold division. In the first place, the peculiarities which they derive from the tissue or part of the body in which they are situated, will require to be discussed, and for this we must refer to separate articles; for instance those on the LYMPHATIC GLANDS, FEMALE BREAST, the BRAIN, BONE, the EYE, the JOINTS, the TESTIS, and the OVARY, in which abscess of those tissues and organs will be described. Abscess also connected with the vertebræ, or with the great muscles of the trunk, will be treated of in the articles on PSOAS or LUMBAR abscess; and the articles on the PERINÆUM, and the GENERATIVE ORGANS in either sex, and the RECTUM will con-

tain an account of abscess in those situations. In the present article we take the other division of the subject, and treat of abscess generally.

Now, as we observe more at length in the article INFLAMMATION, the general characters of each variety of abscess depend on those of the exudation, of which it is the result. Every variety almost, therefore, of blood disorder, may have its own special abscess, and the same may be said of many kinds of local injury.

The first variety we will speak of is the commonest. It is that which arises from the common inflammatory exudation, and which may occur in any constitution, after the blood has been disordered, or overloaded, or the excretions insufficiently discharged; and more especially if some part of the body be in a state which renders it prone to disease. We speak here of the kind of abscess which may follow a bruise or puncture if inflamed; which may affect the female breast during lactation, or the alveoli, if a tooth be decayed. It may occur after fever, or after any other general constitutional disturbance; and in so doing often seems to be the mode in which something injurious may be eliminated from the blood, and the health be improved in consequence. Its course is commonly acute, hence it is often called *par excellence* the *acute abscess*; although sometimes the course of this abscess is chronic; and that of any other variety may be acute. As good a word as any is *phlegmon*.

A second variety, the *chronic abscess*, is marked by the almost entire absence of inflammation, and results from the degeneration of an exudation of a *low*, devitalised kind. The term *scrofulous* is commonly applied indiscriminately to chronic abscesses, although it is not the truth that every chronic abscess is scrofulous, nor that every scrofulous abscess is chronic.

We may remark that abscesses commencing with specific *scrofulous* exudation have characters of their own, which will be pointed out in the article SCROFULA. Chronic indeed they are sure to be in their duration, although their origin may be attended with signs of acute inflammation.

We will only allude to the varieties of abscess which are presented by *boil* and *carbuncle*; to the abscesses which occasionally result from gouty exudations, surcharged with the so called *chalky deposit*, and which also occasionally follow chronic rheumatic disease, if injury be superadded. We might speak of *cancerous* abscess to designate the hollows formed in masses by cancer before ulceration. We must allude to the venereal bubo as an instance of abscess in the lymphatic vessels or glands, or in the areolar tissue around them, produced by the action of a particular poison, through which the *behaviour* (as chemists would call it) of these abscesses has some peculiarities. (See SYPHILIS, CARBUNCLE, CANCER, &c.)

There is another kind, the *diffused abscess*, which has derived its name from its wide extent, and from the circumstance that the exudation is not limited to one centre, and that when suppuration has taken place, the puriform fluid is not contained in anything like a cyst, but is extravasated or diffused widely along the areolar tissue, into the interstices of muscles, and under the skin. This may arise from the nature of the injury which has caused the abscess; as, for example, when a limb has suffered compound fracture and blood has

been widely extravasated, and offensive discharges penetrate the muscular interstices; or when urine is extravasated, or when some poison, as that of snakes, has been inserted into the areolar tissue. Some cases too of carbuncle, may really be called diffused abscesses, so widely are the unhealthy exudations spread in the areolar tissue. But the most frequent cause of diffused abscess is phlegmonous erysipelas, and the state known as pyæmia, in which it is probable that the blood is impregnated with some putrid poison. Not but that the same kind of abscess may follow any grave fever; thus during typhus, the areolar tissue of a whole limb, from the foot to the nates may be filled with pus.

Now whether we have regard to the nature of the exudations which produce abscess or not, we shall find that the threefold division into acute, chronic, and diffuse, will be a convenient one, as it will show the treatment applicable to the largest number of cases. Most acute abscesses arise from a common inflammatory tendency; most chronic abscesses from a state of debility allied to scrofula; and most diffused abscesses, from the presence of some wide contamination of the blood.

The most frequent situation of abscesses is the areolar tissue, especially the subcutaneous, or intermuscular. But there is no tissue which admits of unhealthy exudations into its interstices, which may not be the seat of the abscess.

It is to be remarked further that, the areolar tissue, just outside an irritated membrane, is often the seat of abscess. The commonest abscesses perhaps which occur, are those situated just external to lymphatic glands, when these glands are irritated by poisonous matter brought to them by their afferent vessels. In the common acne, the exudation and suppuration are usually just external to the sebaceous follicles. In phlebitis, and angio leucitis, in mammary abscess, in erysipelas and eczema, the same thing occurs perpetually. A surface is bathed with unhealthy secretion, or vitiated liquor sanguinis, as the case may be; a portion of this is imbibed and creates abscess external to the membrane: or an unhealthy exudation may be directed both to the surface and to the tissues beneath. But whatever the explanation, the fact remains.

Of all situations of abscess perhaps, as we have just said, the lymphatic glands and the areolar tissue around them are the commonest. They are exposed to the passage of irritating matter through the lymphatics from every sore, abrasion, and interstitial exudation whatever. Hence the frequency of bubo of the groin in syphilis and gonorrhœa, of swelling above the elbow or in the axilla after punctures of the hands; and of the cervical glands from cutaneous disease of the face or scalp; moreover they are the chosen seat of exudation in scrofula, and in almost every state of weakness and cachexia, scrofulous or not. (See LYMPHATIC GLANDS, BUBO, &c.)

Acute Abscess in the Areolar Tissue or Phlegmon begins with the usual signs of acute inflammation. Let us suppose that such an abscess follows a local injury, such as bruise, or puncture; that the patient has not kept the injured part at rest, and has been living freely. Pain which gradually increases, and acquires a decidedly throbbing character: heat, swelling, and redness, most

intense at the centre, will be the symptoms. The accession of these symptoms is marked by slight chills, which, as we remark elsewhere (see INFLAMMATION), are the earliest signs of derangement in the blood. These are followed by the usual feverish symptoms; headache, lassitude, quick pulse, hot skin, on which we need not dilate here. The swelling increases, and is exquisitely tender in the centre and œdematous around. During this time, which may vary from twenty-four hours to three days, the affected part is becoming enfiltrated with increasing quantities of exudation;—with blood and liquor sanguinis and fibrine. Now comes the change from the œdematous and adhesive to the suppurative stage. The centre of the swelling becomes softer and more prominent; and tends, as is commonly said, to *point*; its colour becomes of a paler or yellower cast; and if gentle pressure be made with the fingers of each hand alternately a fluid may be felt within, to be impelled from side to side like a wave; hence the term fluctuation. And now, if the part were examined it would be found that the central mass of exudation was softening into pus, that there was a central cavity, containing blood, serum, pus ready formed, and flakes of lymph not quite softened, whilst the exudation around retaining its vital properties forms a pretty definite sac or cyst, by which the pus is circumscribed and prevented from being diffused into the areolar tissue. (See SUPPURATION.)

The abscess being thus fully formed, nature proceeds to get rid of the contents. The parts between the cavity and the skin gradually melt down, the quantity of matter increases, the coverings become thinner, and the pointing and fluctuation more decided. At last the skin becomes tense, portions of the centre look yellowish, and lose their cuticle; at last one or more apertures are formed, and the pus escapes.

Then is presented the spectacle so familiar in idea to the readers of Hunter, of the various effects of inflammation in concentric circles. At the circumference, where the inflammation is least intense, a ring of œdema; within this, a layer of adhesive matter forming the cyst; within that, suppuration; and in the centre, a process of ulceration—the natural surgeon—combined perhaps with some degree of sloughing, in order that the results of the inflammatory process may be got rid of.

In the case of abscess, thoroughly idiopathic, that is, depending on some morbid state of the blood, and not preceded by local injury, uneasy constitutional symptoms may exist for a certain time previously. Perhaps the patient is recovering slowly from the effects of a fever; perhaps the case is one of a woman in imperfect health, taxing her digestive organs to supply material for nursing an infant; perhaps there have been headaches, or pains in the side, or wandering pains in bones or joints, but in such a case shivering is the first symptom; pain in the part affected follows; and these symptoms may come with the greatest suddenness. The writer has seen a case of a lady, rather out of health and weakly, who was seized with shivering, and became delirious in an hour: acute inflammation of one breast followed. In some cases, idiopathic abscess is preceded by a patch of eczema or by some other cutaneous eruption; but in many cases the suddenness of the first local pain is remarkable.

The constitutional symptoms during the suppuration are very variable. In most cases, so soon as suppuration has taken place, it seems as if the disease had done its worst, and was pacified; feverishness abates, and pain ceases or changes its character. This can only be if the abscess be seated in loose and extensible parts. If it be confined by tendinous or fascial structures, which do not bulge out before the matter, nor are softened and disintegrated (absorbed, as the older surgeons said) without great difficulty, then the pain increases continually in intensity till relief is obtained.

One other constitutional symptom there is which demands more examination than is often given to it. We have said before and elsewhere (see INFLAMMATION), that shivering appears to be one of the earliest signs that some grave alteration is taking place in the blood, that something is received into the veins which directly affects the composition of that fluid, or that some change is taking place by virtue of a deleterious substance previously received. For example, no matter when or how a man imbibes the poison of fever or erysipelas, he will feel a shivering when the mischief is beginning in good earnest; and, in like manner, the onset of the inflammation which precedes abscess is commonly marked by a shivering.

But there is another kind of shivering which may accompany suppuration, and which occurs when matter is pent up and cannot escape; more especially if, as we may presume, that matter contains some noxious ingredient. It is often taught in surgical books and lectures, that rigors are a sign of suppuration; but this is not absolutely true, because, if we except the shivering which occurs at the commencement of the case, before any pus is formed at all, the subsequent stages of most abscesses are marked by no rigors whatever.

The fact is, that under certain circumstances, rigors occur after suppuration has occurred; and they show what, in the language of the students of the Hunterian epoch, would be called irritation of the constitution at a disease which cannot be overcome; and what, in the language of the humoralists of the present day, would be interpreted as absorption of deleterious matter from an abscess which has no vent.

The rigors of suppuration form the cold stage of true *hectic fever*. They generally come regularly at the same hour every day; they are followed by a hot stage, and afterwards by a profuse sweat of a disagreeable smell. The pulse becomes quick, the tongue red and raw-looking, and there is a tendency to diarrhoea.

The following case will show the true nature of these symptoms:—The writer was consulted by a lady for *ague*. She had had two fits, on two successive days, of rigors, in the evening, followed by great headache and heat, and by very great and offensive perspiration during the night. On further inquiry, one breast had been painful the preceding week, and was said to be somewhat swelled and painful now. The breast, on examination, presented an obscure indication of deep-seated suppuration; a bistoury was plunged in, a large quantity of pus escaped, and the rigors returned no more.

Rigors, therefore, do not indicate suppuration purely, nor is the absence of rigors a sign of the absence of suppuration; although, if present, they give strong ground for believing that matter is confined somewhere. (See HECTIC.)

After the abscess has burst or has been opened,

if the patient is fortunate and of good constitution, the case is at an end. The walls of the cavity fall together, the chasm is filled with pale pink lymph, and cicatrisation may ensue in forty-eight hours. (See *Hunter on the Blood*, c. iv. § 3; *Macartney on Inflammation*, p. 55.)

In less fortunate cases, the discharge may continue, the aperture may enlarge, and the cure be completed by a more or less tedious process of GRANULATION. (q. v.) An unhealed abscess, contracted into a narrow passage, is called FISTULA, or SINUS. (q. v.) If it have a wide orifice, it becomes an ULCER. (q. v.)

There is one part of the history of abscesses which has degenerated into such a dreary commonplace, that it is with difficulty the writer can bring himself to allude to it at all. This is the alleged law, that inflammation is always most intense on the side nearest the surface of the body; that ulceration, or interstitial absorption, has always a tendency to spread most in that direction; in fact, that there resides in the animal body a kind of centrifugal eliminative law, by virtue of which all extraneous matters, including pus, are brought to the surface. “We have, therefore,” says Hunter, “always extraneous bodies of every kind determined to the skin, and on that side to which the extraneous body is nearest, without having any effect or producing the least destruction of any of the other surrounding parts. From this cause we find abscesses, &c., whose seat is in or near the centre of a part, readily determined to the surface on the one side and not on the other; and wherever the lead is once taken, it immediately goes on.” So far, Hunter affirms a universal law, to the effect that “one side only of the surrounding living parts is susceptible of this irritation, therefore one side only is absorbed; and this is always the side nearest to the external surface of the body.” But, with characteristic carelessness, he immediately afterwards states, that “as some parts *from their structure* are more susceptible of this irritation than others, we find that those parts composed of such structure are often absorbed although they are *not in the shortest road to the skin*; this structure is the cellular membrane, as will be taken notice of hereafter.”

The most probable account of the matter is, that some tissues are more prone to be the seat of exudation than others, and, *par excellence*, the subcutaneous areolar tissue; that some tissues resist infiltration and subsequent softening—possibly by virtue of their mechanical properties, as fascia, muscle, artery, and vein; and, consequently, that an exudation will rather increase in the direction of the skin, amongst the tissues easily admitting of it, than through muscle.

The tissues which are most easily infiltrated and softened down in suppuration are those also which ulcerate most easily—skin, areolar tissue, and the mucous membrane, to which must be added bone and cartilage; but arteries, veins, glands, and muscles are comparatively unaffected, and often appear in abscesses and ulcers with their surfaces as if cleanly dissected. Yet there is no tissue whatever which may not suppurate under some circumstances.

The *chronic abscess* is the result of a very low degree of inflammation, or of none. It is a mere symptom; a consequence of some slow disease of bone or of ulceration of mucous membrane, or

of some other slow degeneration in a constitution marked by want of power.

The patient usually complains first, of a swelling, which is pale, free from tenderness, not adherent to the skin, evidently encysted. In various situations, such a swelling may be mistaken for a venous cyst, a ganglion, an aneurism, or a hernia. The patient probably can give no account of its origin, unless it arises from disease of the spine, or implicate some of the great muscles of the limb, when probably there will be an account of obscure pain and weakness for months or years; in most cases the presence of the tumor is discovered by accident.

The abscess is bounded by a cyst, pale grey or ash coloured, more or less vascular, composed of adhesive or fibrous exudation. The contents may embrace every variety of pus or puriform fluid, in every stage of degeneration. They may be merely an opaque serum, or serum with curdy flakes, with flakes of cheesy matter and cholesterine, or genuine pus. The contents may vary from time to time; they may be diminished by absorption; or increased by fresh exudation kept up by the original source of the disease, or supplied by the inner surface of the cyst;—and this additional exudation may consist of blood or pus, which were not present at first.

One character of chronic abscesses, is their tendency to almost indefinite enlargement before coming to the surface and bursting. An abscess originating in diseased bone may excavate all the areolar tissue of the hips and lower part of the back, and both thighs, and contain gallons of matter. They may also make their way along the interstices of muscles, and point in the most unexpected situations at a distance from the focus of mischief.

As regards local history, the usual course is, that so soon as the chronic abscess has become sufficiently large to stretch the skin and interfere with its nourishment, the distended part reddens, and soon ulcerates at one or more points, just as in the case of an acute abscess, and the matter is discharged.

But this process admits of very many varieties in its circumstances and results and in the constitutional symptoms attending it; the chief of which are the following:—

In the first place, if the abscess result from an insignificant exudation into the areolar tissue, and if the state of health which gave rise to that exudation be repaired by proper alteratives and tonics, then, as we observe in the article ABSORPTION, both the original exudation, and any puriform fluid to which it has given rise by its presence may be taken into the veins again, and the case be cured by absorption.

Secondly, in the case of a small abscess in the subcutaneous or intermuscular areolar tissue, it may burst, or be opened, the pus escape, and then under favourable circumstances, the opposite sides of the cyst may at once contract and adhere, and the aperture heal. But far more frequently there is a want of plastic energy in the lining cyst, so that it requires a long time to contract, during which, as in the acute abscess, the orifice may enlarge into an ulcer, and considerable drain take place from the internal surface. (See also SINUS.)

Thirdly, in the case of a large abscess, there are other and very grave conditions which may be

added. One of these is, that from certain changes in the quality of the matter contained in the sac, the same series of phenomena may occur which we spoke of under the head of acute abscess,—viz. rigors, occurring daily, followed by a hot stage, and profuse perspirations; in fact, the symptoms of acute hectic which we have before detailed. This is not the place to enter fully into the subject of hectic. Well may Hunter's words be taken in their true sense, that "the constitution has become conscious of a local disease or irritation which it cannot remove nor cure." True also was his observation that hectic does not usually come on till after large chronic abscesses are opened; and likewise his opinion that absorption of pus alone cannot be the cause of hectic. But in truth, the word *pus* embraces an immense variety of morbid products, which again may be intermixed with products of decay; and these if absorbed, may be capable of causing hectic. We may observe, as we have before said, that rigors and the other signs of hectic may exist without suppuration; and that suppuration to an enormous extent may exist without them: further that pus may be and daily is absorbed without producing hectic; yet that pus in certain stages of decay or varieties of admixture may if absorbed cause these symptoms, and does actually produce them under certain circumstances. Some modern surgeons have copied Hunter and fallen into the error of asserting that hectic *never* occurs till after an abscess is opened. But this is absurd.

The symptoms then of hectic, rigors, heat, perspirations, red tongue, thirst, loss of appetite, diarrhœa, aphthæ, pink sediment in the urine, loss of hair and rapid emaciation may occur before an abscess has been opened. But after a large abscess has been opened a worse train of circumstances arises, which renders hectic in its severest form still more likely to come on. The surface of an extensive cyst, endowed with very feeble vitality, is deprived of the support heretofore rendered to it by the liquid which it contained. Hence its surface becomes loaded with blood; and its feeble vessels giving way, exude more or less blood or serum. The injury thus occasioned sets up some degree of inflammation and feverishness. Air probably gains access to the interior of the sac, and the pus, a liquid not easily putrefiable by itself, is rendered eminently so, by being mixed with small quantities of serum and blood. Hence there is a large internal absorptive surface, bathed in putrescent fluid. And now follows a more grave set of symptoms. The patient up to the very day of the opening of the abscess, may, with the exception of debility, have been in a comfortable state of health; he may have escaped all hectic hitherto, for, as we have said, that condition appears to be incidental to abscess, and not essential, to arise from the absorption of pus in particular conditions, and not from absorption of pus *pure* and *simple*. But let the interior of a large sac be bathed with putrid matter, and then comes on shivering, picking of the bedclothes, dry brown tongue, restlessness, possibly sickness, probably diarrhœa, which after two or three days will be followed by death.

Lastly, it must be noticed, that the drain from an extensive abscess may slowly bring on complete exhaustion, even though there be none of the signs of blood poisoning just related.

The *diffused abscess* now comes to be described,

and if it be true that all other abscesses are but symptoms of some local or general morbid condition, more especially may the same be alleged of this. There are, as we observed before, two kinds; one produced by local injury, such as infiltration of the areolar tissue with urine, or with fetid exudation from a wound or some other poison; the other resulting from the action of the more violent blood poisons, which cause wide exudation of a matter difficult of absorption, prone to run into a state of liquefaction, and incapable of becoming organised, like healthy fibrine into a sac, which shall circumscribe the liquid part of the exudation and prevent its wide diffusion. (See INFLAMMATION.)

The points in which the diffused abscess differs from the common acute abscess, are these:—Swelling is flatter, more widely spread; not elevated in one centre;—redness also not most intense at the centre, and gradually vanishing, but extending in irregular patches; perhaps abruptly defined;—redness sometimes absent;—sometimes of a peculiar and unusual hue; heat and pain are generally intense; in some cases they may be absent. Want of tendency to point in one place; and a hard brawny, or a doughy, or œdematous, or obscurely fluctuating swelling are other characteristics.

The local progress of this kind of abscess is as follows:—First comes unhealthy exudation, which spreads and infiltrates the areolar tissue. It may be firm and brawny; or almost entirely liquid from the first, consisting of a turbid yellowish serum. It may occupy great space and extend great distances, filling the entire subcutaneous areolar tissue of a limb, or of one side of the trunk. It soon causes inflammation of the skin, whose vitality is seriously interfered with from the state of the subcutaneous tissue, and which exhibits vesicles filled with serum, straw coloured, or yellow, or livid. At these points the skin afterwards ulcerates or sloughs, giving exit to copious puriform discharge, with flakes of dead areolar tissue which come away often like masses of wet tow. Large tracts of skin may perish in this way, and all the areolar tissue may perish from the surface and interstices of the muscles, leaving them as though cleanly dissected. The work of granulation may succeed vigorously, but cicatrisation must of necessity be slow under such circumstances, and the muscles be left embarrassed and the joints permanently bent.

The constitutional symptoms which accompany such a state of things are those which are sometimes described as symptoms of *irritative fever*, or *pyæmia*; or of *typhoid symptomatic fever*. Rigors followed by intense excitement of the heart; palpitation and anxiety at the chest; rapid soft pulse; dry brown or glazed tongue; possibly bilious diarrhœa, or dysentery; possibly delirium; possibly a preternatural calmness and clearness of mind. If relief be not given, the patient sinks, and death is perhaps preceded by squinting and convulsive twitchings.

The great variety of causes which may give rise to diffused abscess must of necessity occasion great difference in the details. These may be learned by consulting the articles EXTRAVASATION OF URINE, COMPOUND FRACTURE, GUNSHOT WOUNDS, POISONED WOUNDS, and DISSECTION WOUNDS; whilst the details of cases arising from constitutional causes will appear in the articles PYÆMIA, ERYSIPELAS, and GLANDERS.

In cases in which the malady arises from a vitiated state of the blood, operating on parts which have received no injury, it is surprising how suddenly the whole process may be accomplished. A woman, for instance, whose womb has imbibed an erysipelatous poison after child-birth, and who has shivered, and is suffering from abdominal pain and tenderness, and suppressed milk and lochia, may be struck as it were with a sudden pain in one shoulder or elbow, which after a short time may vanish entirely, and be succeeded by pain in the calf of the leg, which speedily reddens, and in a few hours may be a bag of pus; and in some cases this is accomplished with little if any pain.

From cases of this kind the student may learn the purport of various terms which have been applied to abscesses. For example, a distinction may be made between abscess *in* a part, and abscess *of* a part. In the former, suppuration occurs in a part previously healthy, which is selected as the spot for accomplishing a work of elimination; in the latter, the suppuration is produced by a diseased state of the part itself. Abscesses by which the separation of a materies morbi was assumed to be effected were formerly often called *critical*; they have also been termed *consecutive*, and *metastatic*; although the last word, in its ordinary signification implies more than can quite be proved; that is, it implies that pus, in the form of pus, is taken up from one part and deposited in another, of which there is no proof. (See PYÆMIA, PHLEBITIS.)

One kind of abscess may improperly be called diffused; and that is abscess underneath hard fasciæ, and in the sheaths of tendons; the pus cannot get through these, and so spreads underneath them; and very serious cases they are; but their diffusion arises from anatomical peculiarities, and not from any thing special in the kind of exudation.

We have now described the three chief forms in which abscesses may present themselves, no matter from what cause they may arise. But it must be borne in mind that innumerable shades and gradations exist; for example, in the intensity of the inflammation which shall accompany the first stage of an abscess, and in the degree of blood contamination which shall be the cause of it; and that allowances must be made, in this as in other cases where things are treated of in a general way, for the difficulty of presenting one set of facts without seeming to ignore another. Every gradation may occur between a *healthy* acute abscess, concentrated to one point, rapidly suppurating, pointing, bursting, and healing up; and the *unhealthy* diffused abscess, with its imperfect limitation, and suppuration in patches here and there, and widespread destruction of the areolar tissues. So every variety may exist, in the degree of *healthy* sthenic feverishness, and of *unhealthy* *irritative fever*; and every variety between the acute and chronic abscess in the amount of vigour and rapidity with which the diseased processes are begun, carried on, and ended.

On the *causes* of abscess we need not dwell largely, as they embrace all the causes of local inflammation. Suffice it to say, they may be classified under these three heads:—1. Abscess resulting purely from the localisation of blood disorder, including all scrofulous, and cachectic, and critical, and eliminative abscesses; all abscesses resulting

from pyæmia, glanders, and all the pustules of small-pox. 2. Abscess resulting from local injury; such as punctures and bruises; whether or not complicated with the presence of foreign bodies, or impregnated with poison. 3. Abscess resulting from pre-existing disease of another part, from disease of bone or joint, or from ulceration of mucous membrane of rectum, urethra, or the like.

Treatment of the Acute Abscess.—This may be divided into four branches:—1st. Measures which may be adopted to prevent suppuration, supposing it has not taken place, or to cause absorption of the matter, supposing it has. 2ndly. Measures intended to promote and hasten suppuration. 3rdly. The evacuation of the matter where formed. 4thly. The cure of the resisting cavity or ulcer.

In the first place, then, if any given case of inflammation is seen early, it will be fair to consider whether the patient may not be spared the pain and injury which would result from allowing it to go on to suppuration. Let us suppose, as before, an inflamed bruise or puncture, or other local injury. In this case the treatment of inflammation adapted to the case must be put in force. The part must be kept at rest, and elevated; leeches applied; warm poppy fomentations, or cold lotions be used; (and the patient, as stated elsewhere, may be safely left to make his choice;) and, above all, a dose or two of calomel, with colocynth or senna, or Epsom salts, must be administered. By these means, probably, the inflammation may abate; should it, however, still go on to suppuration, the case must be treated as described presently.

If the case be purely idiopathic, and be seen early, the practitioner must make it his duty to consider of what particular blood disorder the local inflammation is a sign, and whether he may not get rid of the materies morbi, through some of the great secreting organs. For example, a patient recovering from fever is seized with violent pain deep in the neck, with obscure swelling, intense tenderness, and utter inability to move, and with great feverishness. Another patient has the same symptoms on the lower and inner part of the thigh. Another is seized with pain and swelling of the gums near a carious tooth. These symptoms, we are certain from experience, if unchecked, will go on to abscess. But by attending to the common principles of the treatment of inflammation, by purifying the blood, and abating local irritation, they may be made to subside.

The first point is to produce a good discharge of bile and faecal matter, by repeated doses of calomel, carried off by purgatives, till offensive, dark-coloured motions have ceased to pass. Meanwhile the patient should be in bed; the part raised, and covered with warm fomentations or poultices of bread, bran, linseed, or boiled chamomile flowers. No matter what theory may say, there is no doubt but that warmth and moisture are capable alike of facilitating the dispersion and the maturation of abscesses in the proper cases. The diet should be just what is requisite to keep the powers up to a healthy standard; it may require to be low, middle, or high. Leeches also may be applied if the pain and tenderness are intense.

By these means, supposing all active inflammation to have subsided, the pulse to be quiet, and the tongue clean, and the inflamed part slacker, cedematous, and much less tender, then, whether

suppuration be conceived to have taken place or no, the matter will probably be absorbed, and the case do well. Moderate pressure by bandages, gentle stimulation of the surface with warm spirituous liniments, especially the compound camphor liniment; aperients, quinine, mineral acids, and other tonics, with and above all fresh air and sea-bathing, will most likely finish the cure.

We hear sometimes of specific remedies adopted to hasten absorption, such as the iodine paint, or iodine liniment; vesication with the cantharides or nitrate of silver, or the formation of pustules with tartar emetic ointment, and particularly emetics. The writer believes that if the principles laid down in the preceding paragraph are acted upon, these measures will be found unnecessary; in case of need, however, the surgeon can try them. We purposely avoid here the question of the *Venereal Bubo*.

The remedies adapted to prevent suppuration, may be used in all cases, because if they do not prevent, they will at least lessen the amount of it; except however two most decided repressing remedies: viz. cold applications and leeches, in the use of which the surgeon shows his discretion, or the want of it. As a general rule, leeches should not be used unless there is something like certainty of preventing suppuration; and cold should not be used in acute idiopathic inflammation generally, unless the patient particularly wishes it.

Our second branch of treatment consists in hastening suppuration, if inevitable. The means are simply abstaining from cold, leeches, and unnecessary purgation: and in the constant application of moist applications, as warm as they can be borne with comfort.

Our third point relates to the evacuation of the matter; and in most cases it is best to quicken the operations of nature, by opening the abscess. It is, or was commonly said, that abscesses may be opened by the knife, by caustic, or by seton. Setting aside the last as a barbarism, and observing that the caustic is of service in cases where the skin covering an abscess is thin and sure to ulcerate, as in some buboes and carbuncles, so that the surgeon does quickly by caustic what otherwise could be done more slowly and painfully without;—we may state that the best instrument is a small straight knife, which should be plunged in at the place where there is most pointing, till it has entered the cavity, and then be made to cut half an inch to an inch and a half, as it is being withdrawn. Then the swelling should be fomented, and covered with warm soft poultices, into which the matter may escape, solicited by gentle pressure.

The size of the aperture should be such that the matter may run out easily, and if the case admits of choice, it should be in a *depending* posture.

Fourthly. After the evacuation of the matter, poultices and fomentations may be continued for a day or two, until tenderness and pain cease; then lint, dry or dipped in zinc lotion, and bandage, are the best applications, and the health should be recruited with good diet and tonics.

Treatment of the Chronic Abscess.—In all cases, the constitutional treatment takes precedence, and it will be the practitioner's duty to prescribe sea-air, steel, cod-liver oil, iodide of iron or of potassium, and such other alteratives and tonics as

may be best adapted to the circumstances of the case. He must further bear in mind the duty of looking for local disease, especially of bone, to which the origin of the abscess may probably be traced; and likewise the dangers which arise from the fact of the existence of a large abscess, no matter what its cause may be.

Speaking generally, we may say that in all cases, the sooner an abscess is opened the better. Many remedies, local and constitutional, are spoken of as capable of producing absorption, but the less the practitioner trusts to them, the less he will be disappointed. Galbanum plaster, iodine paint, and the like do little good.

So soon as the diagnosis is certain, especially if the tumour is enlarging, and has become adherent to the skin, and certainly before the skin is inflamed or rendered liable to ulcerate, an opening should be made.

If the abscess be superficial and small, not connected with deep-seated disease, it should be opened freely, so that it may be thoroughly emptied, and pressure be kept upon the sac by compresses, strips of plaster or bandages. The wound, after a day or two, may be bathed with zinc lotion, and the cavity be injected with it, if the discharge continues thin and copious; or a solution of nitrate of silver or of iodine, may be employed for the same purpose, to destroy the lining of the sac, and create fresh exudation and granulation with vigour. If the discharge continues to get less and less, and there is no particular inconvenience, the cavity may be left to shrink under the influence of moderate pressure.

There is an untoward event which sometimes occurs to chronic abscesses of scrofulous origin, and that is the deposit of additional scrofulous exudation outside the abscess, the ulceration of the orifice, and conversion of it into a scrofulous ulcer, which is always a most tedious affair.

If the abscess has already become perilously large, the great point is to make it smaller before it becomes permanently open, and to avoid the dangers of inflammation of the cyst, and absorption of putrid matter. For this purpose a small opening should be made with a trocar or bistoury: the greatest care should be taken to keep up gentle pressure during the operation, so as to keep out the air; a bandage should be put on so as to maintain equal pressure on the cyst, and the wound should be most accurately closed by plaster or collodion, or bloody lint moistened with a little perchloride of iron, and be made to heal. After a few days, another opening should be made with the same precautions, and it should be repeated at such times as will not allow the cyst to return to anything like a state of distention. By this process, it may be hoped that the sac will gradually contract, so that at last if a permanent sinus be established, it may do no harm.

If putrefaction of the contents of the sac should take place, not a moment should be lost in making free openings, so that there may be no retention, and in syringing out the cavity with weak solution of chloride of lime, and adopting every means of keeping the veins full of good wine and soup, so that absorption of the putrid matter may do less harm.

Treatment of the Diffused Abscess.—For the details of treatment we must refer to the Articles which we have referred to for details of symptoms. Here we may say briefly, that early and free inci-

sion into the infiltrated tissues, and the use of tonics and abundant diet with stimulants, and of small doses of mercury to provoke the eliminative organs (not to affect the mouth) in cases in which there is infection of the blood, are the leading measures.

The following aphorisms from the earlier edition of this dictionary, well deserve the attention of the surgeon.

OF THE TIME WHEN ABSCESSSES SHOULD BE OPENED.

The following are generally regarded as cases in which an opening should be made, as soon as the slightest degree of fluctuation is perceptible, or sometimes even sooner.

1. Abscesses arising from extravasation or effusion of irritating fluids or matters into the cellular tissue. To this class especially belong urinary and faecal abscesses. Here the incision is necessary, not only for the discharge of pus, but of the effused matter, or fluid, which is the cause of irritation and suppuration. I may add, that, under such circumstances, a very free incision is required to fulfil these two important indications.

2. Abscesses preceded by intense inflammation, and situated in parts abounding in adipose cellular tissue; as, for instance, the verge of the anus, the neighbourhood of the rectum, the sides of the neck, and the axillary, inguinal, and popliteal regions. In such cases, if an early opening be not made, the purulent matter spreads to a great extent in the cellular tissue, and an enormous denudation of parts, or separation of them from one another, is apt to ensue.

3. Daily experience teaches the surgeon, that abscesses are seriously retarded in their progress to the surface of the body by the intervention of a fascia, or an aponeurosis. These are cases, therefore, requiring an early opening to be made, in order to prevent the matter from spreading widely in the interstices of the muscles, from detaching the vessels and nerves from their connexions, and from forming numerous and extensive sinuses in various directions. Abscesses under the fasciæ of the thigh, arm, forearm, and leg, come under the rule here specified, as well as collections of matter under the palmar and plantar fasciæ, and in the sheaths of tendons. Here, as Dupuytren observes, the practice of an incision is warranted as soon as the practitioner perceives œdema of the parts, a broad and undefined swelling of them, the phenomena attending the progress of internal abscesses, and a deep obscure fluctuation, following the ordinary symptoms of inflammation.

4. Abscesses in the parietes of the chest, or abdomen, in the vicinity of a serous membrane, should be opened without delay, in order to prevent with certainty the effusion of pus inwardly, an occurrence which, though rare, has sometimes happened. Certain abscesses of the neck, formed under the sterno-cleido mastoid muscle, call for an early opening; because they not only cause a considerable and very painful swelling, but the matter may easily descend towards the clavicle and chest, in the course of the vessels and nerves.

5. Abscesses in parts abundantly supplied with nerves and capillary blood-vessels, and which, when inflamed, are accompanied by excessive pain or close confinement or strangulation of the textures, as whitlows, large painful boils, carbuncles, &c.

6. All abscesses producing serious disturbance, or interruption, of the functions of very important organs, and thereby endangering life; as abscesses of the throat, or near the larynx, or pharynx; abscesses compressing the jugular veins, and threatening the patient with apoplexy or suffocation, &c. In such cases, if the practitioner were to defer making an opening until the swelling had softened, and the abscess had been perfectly formed, the patient would be in great danger of perishing ere such changes had taken place.

7. The generality of chronic abscesses should be opened early, more especially if the means usually resorted to for promoting the absorption of the matter, present no prospect of success. By omitting to make an outlet for the matter, we allow the accumulation of it to increase, and sometimes the abscess then becomes dangerous from its mere size; the inner surface of it, or the cyst, acquiring vast magnitude. With respect to chronic abscesses, connected with diseased bone or diseased joints, and collections of purulent fluid in the synovial membranes, some directions will be found in other parts of this work. (See JOINTS; LUMBAR ABSCESES; VERTEBRÆ.)

"Those abscesses ought to be opened early (says Professor Thomson) that are situated in parts through which the matter is liable to become widely diffused. This is particularly the case with abscesses that are situated on the fore part of the neck, or in the cavity of the axilla, or by the side of the rectum. When matter is formed in the cavity of the axilla, if it does not speedily obtain an external outlet, it is very liable to pass up towards the clavicle in the course of the axillary plexus of nerves and vessels, or forwards under the pectoral muscle. I have repeatedly seen axillary abscess take both of these directions at the same time, forming one of the most painful and difficult cases to treat, which occurs in the management of abscesses." Dr. Thomson also considers an early opening proper and necessary, when the matter is lodged, as in some cases of whitlow, in the sheaths of the tendons; when matter is formed under the periosteum; when it collects under fasciæ, or in the vicinity of large arteries, joints, or the greater cavities of the body; and also when the abscess is deep-seated. (See *On Inflammation*, p. 336—338.)

With respect to making an early opening into abscesses situated near large arteries, I am not aware that any danger of the artery ulcerating in consequence of the nearness of the pus, really exists. Therefore, some doubts may reasonably be entertained of the soundness of Professor Thomson's advice in this particular case, as the general rule of opening abscesses near large blood-vessels, in an early stage of the disease, would be objectionable on the ground of the practice exposing the vessels themselves to injury. Indeed, this well-informed writer distinctly mentions, in considering the subject in question, that the arteries are not very susceptible of ulcerative absorption (p. 337).

It is now a well-established fact, that arteries, and veins likewise, may ulcerate into the sac of an abscess, particularly if of the scrofulous kind. (For examples, see the *Med-Chir. Trans.* vol. xxvi. xxix.; South's Edition of Chelius, I. 191.) Moreover abscesses may burst into any serous or mucous surface that happens to be near; lung, bowels, pleura, or peritoneum.

The making of an opening in certain abscesses should be deferred longer than in common instances. Such are collections of purulent matter, situated in internal organs, as the liver, spleen, kidney, and lungs, and producing an outward swelling. Dupuytren deems it most prudent not to open such tumor until the skin is inflamed, the only circumstance which can be depended upon as denoting the formation of those adhesions, by which alone the insinuation of the pus into the great serous cavities will be prevented. — [*R. Druitt.*]

ABSORPTION. This word signifies the process by which any substance whatever, solid, liquid, or gaseous, passes into the blood-vessels of a living animal. It is used, also, by writers of the past generation, as synonymous with atrophy, emaciation, or wasting.

The idea of absorption is so associated in the minds of most surgeons, with the name of John Hunter, that we will commence by giving an account of the very elaborate doctrines which this great man taught, although they are now quite superseded by the more simple and truthful views of the present generation.

The leading idea, which runs through all Hunter's speculations on this matter, is, that absorption is an active process, an operation, or action, performed by the *mouths* of the lymphatics, or, as he calls them, the *absorbent* vessels. "My conception," he says, "is that the whole operation of absorption is performed by an action in the mouths of the absorbents." "Physiologists," he says, "have supposed that the action of these vessels was similar to that of capillary tubes. But capillary tubes can only imbibe liquids, whereas solid matters, such as scirrhous tumors, and bones, may be removed by the absorbents. "Therefore," he continues, "unless we assume the existence of some solvent, to reduce these solid parts to a liquid state, such as would enable them to be imbibed by capillary tubes (which we have no proof of), we must suppose some action in the mouths of the absorbent vessels, capable of effecting the same purpose." "Consider," he says, "the mouths of different animals, and I will venture to say that the mouths of all the different animals have not a greater variety of substances to work upon than the absorbents have; and we may observe that with all the variety of mouths in different animals, this variety is only for the purpose of enabling them to absorb solids, which admit of every variety of form, texture, &c., every one being capable of absorbing fluid matter, which admits of no variety."

Such, in Hunter's own language, were his ideas of the mechanism of absorption, and the action of what he called the *absorbent* vessels.

Respecting the uses and operations of these vessels, he considered them (to use his own words) "in two views; first, as they absorb matter which is no part of the machine; secondly, as they absorb the machine itself.

"The first of these is the well-known use, the absorption of matter which is no part of the machine. This is of two kinds; one, exterior matter, in which may be reckoned everything applied to the skin, as also the chyle; and the other, interior, such as many of the secreted juices, such as fat, and the earth of bones, &c. These are principally with a view of nourishment, and also answer many other purposes; so that the action of absorbing

foreign matter is extremely extensive, for, besides its salutary effects, it is often the cause of a thousand diseases, especially from poisons.

"In the second of these views we are to consider them as removing parts of the body itself, in which they may be viewed in two lights. The first is, where only a wasting is produced in the whole machine or part, such as the wasting of the whole body from an atrophy; or of a part, as the wasting of the muscles of the leg, &c. from severe injury done to some nerve, tendinous part, or joint, all of which I call interstitial absorption, because it is removing parts of the body out of the interstices of the part which remains, leaving the part still as a perfect whole. But this mode is often carried farther than simply wasting of the part; it is often continued till not a vestige is left, such as the total decay of a testicle, so that the interstitial absorption might be understood in two senses.

"The second is, where they are removing whole parts of the body. This may be divided into the natural and the diseased. In the natural, they are to be considered as the modellers of the original construction of the body; and if we were to consider them fully in this view we should find that no alteration can take place in the original formation of many of the parts, either in the natural growth, or that formation arising from disease, in which the absorbents are not in action and take not a considerable part; this absorption I shall call modelling absorption. If I were to consider their powers in this light, it would lead me into a vast variety of effects, as extensive as any principle in the animal economy, for a bone cannot be formed without it, nor probably many other parts. A part which was of use in one stage of life, but which becomes entirely useless in another, is thus removed. This is evident in many animals; the thymus gland is removed, the ductus arteriosus and the membrana pupillaris are removed.

"Absorption, in consequence of disease, is the power of removing complete parts of the body, and is in its operation somewhat similar to the first of this division, or modelling process, but very different in the interstitial, and therefore in its ultimate effects. This process of removing whole parts in consequence of disease, in some cases produces effects which are not similar to one another; one of these is a sore or ulcer, and I therefore call it ulcerative; in other cases, no ulcer is produced, whole parts are removed, and for this I have not been able to find a term; but both may be denominated progressive absorption.

"This process of the removal of a whole solid part of the body, or that power which the animal economy has of taking part of itself into the circulation, by means of the absorbing vessels, whenever it was necessary, is a fact that has not in the least been attended to, nor was it even supposed; and, having now been noticed, I mean to give a general idea of it. I may just be allowed once more to observe, that the oil or fat of animals, and the earth of bones, have always been considered as liable to absorption; and some other parts of the body being liable to wasting have been supposed to suffer this by absorption; but that any solid part should totally be absorbed is a new doctrine. This use of the absorbents I have long been able to demonstrate; and the first hints I received of it were in the waste of the sockets of the teeth, as also in the fangs of the shedding teeth.

"It may be difficult at first to conceive how a part of the body can be removed by itself, but it is just as difficult to conceive how a body can form itself, which we see daily taking place; they are both equally facts, and the knowledge of their mode of action would answer perhaps very little purpose; but this I may assert, that whenever any solid part of our bodies undergoes a diminution, or is broken in upon, in consequence of any disease, it is the absorbing system which does it."

Thus, according to the views of Hunter, all absorption whatever, and all processes of diminution of bulk or loss of substance, are due to the action of the mouths of lymphatic or absorbent vessels. They were believed to absorb chyle for nourishment, as well as poisons and medicines; they were the causes of emaciation of the whole body under illness, and of wasting of any part of the body from disease; they acted as the pruning knife, to check exuberance of growth; they were the means through which bones or other parts were wasted before an encroaching aneurism or tumor, and by means of which abscesses were brought to the surface; lastly, they were the agents by which ulceration was produced; "a process which," says Hunter, "answers very material purposes in the machine, without which many local diseases could not be removed, and which, if allowed to remain, would destroy the person. It may be called in such cases *the natural surgeon*."

"It is by the progressive absorption that matter, or pus, and extraneous bodies of all kinds whatever, in consequence of or producing inflammation and suppuration, are brought to the external surface; it is by means of this that bones exfoliate; it is this operation which separates sloughs; it is the absorbents which are removing whole bones, while the arteries are supplying new ones; and although, in these last cases of bones, it arises from disease, yet it is somewhat similar to the modelling process of this system in the natural formation of bone; it is this operation that removes useless parts, as the alveolar processes when the teeth depart or when they are removed by art, as also the fangs of the shedding teeth, which allow them to drop off; and it is by these means ulcers are formed." (*Hunter on the Blood*, chap. vi.; Palmer's edition, vol. iii. p. 463.)

In order to make our account of the Hunterian doctrine complete, we must add a few lines on his doctrine of the causes of absorption and disposition thereto.

The *final* cause or purpose of absorption is, he says, the removal of that which is useless or injurious; anything therefore which renders parts useless, or which so disturbs the vitality of parts as to render them unable to support themselves, are efficient or remote causes.

"The most simple object or intention of nature seems to be the removal of a useless part, as the thymus gland, membrana pupillaris, ductus arteriosus, the alveoli when the teeth drop; as the crystalline humour after couching, and probably the wasting of the body from fever, either acute or hectic. These parts are removed by the absorbents, either as useless parts, or (in the latter case) in consequence of strength being unnecessary while under disease, or such as not to accord with disease.

"It might be asked, as a question, whether the waste of the constitution in disease arises from the

body becoming useless when under such treatment, as may be observed of muscles when their joint, tendon, &c., is diseased, or whether it accords better with the diseased state, and may even tend to a natural cure.

"From the above account of the final cause of the absorption of whole parts from disease, it would appear that they are capable of being absorbed from five causes. First, from parts being pressed; secondly, from parts being considerably irritated by irritating substances; thirdly, from parts being weakened; fourthly, from parts being rendered useless; fifthly, from parts becoming dead.

"The dispositions of the two parts of the living body," continues Hunter, "which absorb and are absorbed, must be of two kinds respecting the parts, one passive and the other active. The first of these is an irritated state of the part to be absorbed, which renders it unfit to remain under such circumstances, the action excited by this irritation being incompatible with the natural actions and existence of the parts, whatever these are, which therefore become ready for removal, or yield to it with ease. The second is, the absorbents being stimulated to action by such a state of parts, so that both conspire to the same end."

We have thus, at some length, and in his own language, detailed Hunter's doctrines of absorption, because, as we have before intimated, they form, as it were, part of the very basis, of the very substratum of principles which have been accepted by members of the profession, whose studies were carried on before the modern chemical and microscopic era. They form a great fact in the history of medicine, and even though now superseded, they deserve to be recorded, partly as an element of the progress of opinion, partly because amidst their error they present a certain grandeur of conception, and because they illustrate the mode in which one false step in reasoning may be the parent of infinite confusion.

We may pass over that incessant attempt to demonstrate final causes, which is so characteristic of Hunter, and in which he is sedulously imitated by a crowd of writers, who deceive themselves with the idea that they can penetrate the purposes and intentions of the Creator, although it is hardly possible to suppress a smile at the extravagant notion of an elaborate machinery being provided to effect the emaciation of illness, on the ground, that "strength is unnecessary while under disease." We may pass over also the extravagant *solidism*, which refers every change to the *action* of organs, and takes no account of their composition. Suffice it to say, that the very foundation of the doctrine is a mistake. The universal existence and agency of absorbent vessels, with or without mouths, is neither proved nor probable, and all the hypotheses of their various effects are so many dreams.

In fact, as Mr. Lane observed (in his article on the Lymphatics, *Cyclop. Anat. and Phys.* 1841), we may "confine the functions of the lymphatic system within the bounds ascribed to the lacteal vessels during the process of digestion, viz. to select and prepare nutritious materials for the purpose of sanguification." Moreover, as Mr. Lane says, "we are going too far in attributing to the lymphatics the important and universal function of interstitial absorption in the process of growth and nutrition; and it is without sufficient proof

that we admit the ulcerative process to be carried on solely by the lymphatic system." And it is curious to observe, that in the midst of Hunter's strong assertions of the fact of their operation, and his claims of being the first to announce it, he never once seems to feel it necessary to bring forward any proof whatever of the truth of what he asserts.

Let us now rapidly enumerate the various processes in the human body, which may be denominated by the term absorption; after which we shall make a few observations on the manner in which foreign substances may be introduced into the circulation, and the manner in which that introduction may be prevented; and then on the cases in which the surgeon is interested in the absorption of parts of the body, or of fluids infiltrating these, and on the medicines most calculated to produce that kind of absorption.

And in the first place let us remark, that *absorption may be considered in two lights, an active and a passive*. It may be considered, as Hunter considered it, an action, an operation, a work done by the agency of some instrument; or, on the other hand, as a mere passive or negative process; as a thing suffered.

If, for example, we speak of the lacteals selecting certain materials from the contents of the intestine, taking them into their own tubes by a particular mechanism, and passing them onwards, we speak of an active process, a work done by certain instruments.

When, on the other hand, we speak of the imbibition of any vapour by the lungs, or of any liquid by the skin, which those parts, by virtue of their physical conformation, cannot help imbibing if presented to them, any more than blotting-paper can help sucking up ink; or when we speak of loss of substance and *dépérissement*, which the whole body or any part of it suffers if deprived of its nourishment, it is evident that these processes are merely passive or negative. A poisonous vapour penetrates the substance of skin always, and this not by any action of those parts as living, but by virtue of their composition whether living or dead. To speak, too, of the wasting of illness as an absorption, when it is merely the negation of nourishment, is surely an abuse of the term.

Now most of the cases described under the title *absorption* are of the negative or passive kind.

In the first place there is the imbibition, which takes place through all surfaces, of matters presented to them, whether liquid, or gaseous, or solid if divided to a sufficient degree of minuteness. Physical imbibition, by virtue of porosity and of mutual attraction between the imbibing membrane and the gas or liquid imbibed, is the proper name of this form of absorption. The imbibition of oxygen by the skin and lungs; the imbibition of water, and of nutrient fluids by tongue, throat, stomach, and every part of the alimentary canal, are examples of this process under the ordinary conditions of health; whilst the absorption of chloroform and similar vapours by the lungs, of hydrocyanic acid by the mouth or skin, of mercury in the form of vapour or ointment, of nutrient or anodyne enemata by the rectum, are examples of the same process, owing either to accident or to the intention of the medical practitioner. But for this kind of absorption no special agents or set of vessels are required; it is a function per-

formed by every animal tissue, by virtue of its physical properties.

In the second place, there is the emaciation of the whole body in illness; or the removal or shrinking of parts rendered useless in the course of nature, as the ductus arteriosus and membrana pupillaris; the formation in the fœtus of the apertures of the eyelids, mouth, and rectum; and the decay of certain organs under conditions of disease; as, for example, the withering of the muscles of a limb which is paralysed; or of certain sets of muscles whose nerve is diseased, as happens sometimes after sciatica. This class of instances ought rather to be designated instances of *atrophy* than of absorption. For it does not happen that the withered parts are absorbed to an extraordinary degree, but that being wasted in the ordinary course of nature, they are not replaced. Just as a house may crumble away under the action of the elements, if never repaired, although no active steps be taken to pull it down. In this class, as in the preceding, there is no evidence that the lymphatic or *absorbent* vessels are in any way concerned.

As a third class of instances of absorption, we may take the cases in which, not a natural structure, but a deposit or exudation, liquid or solid, caused by disease, is removed. For example, the exudation which closes the pupil in iritis, or fills the pleura after inflammation; or a common extravasation of blood in consequence of a bruise. In the case of a morbid exudation, the first condition necessary for its absorption is, that the blood shall no longer be loaded with the materials out of which it is formed; that the gouty or syphilitic, or hyperinotic crisis, as the case may be, shall be extinguished. The second is, that the exudation be not of a sort endowed with independent vitality and power of growth; that it be not developed into permanent tissue. If those two conditions be obtained,—if, for example, the source of a pleuritic exudation be eliminated, before the exuded matter has passed into the permanent form of areolar tissue, the morbid deposit will most likely waste of its own accord. If, as in the case of cancer, both the blood continues to supply morbid material, and the morbid exudation, where deposited, grows and propagates itself of its own inherent forces, there will be little hope of disappearance by absorption.

The instance of extravasated blood ought rather to come under the head of absorption of foreign matters, for it follows the same laws. The serum is first absorbed; then the blood corpuscles are broken down, and the colouring matter dispersed in the interstices of the tissues, which imbibe it; and there it is gradually removed by means of the incessant interchange which is going on between the fluids in the blood-vessels, and those in the inter-vascular spaces, by which the blood is, as it were, after a short time washed out.

In this third class of cases, as in the preceding, there is no evidence that the lymphatic system takes any share in the absorption.

The fourth class of cases, is one of those which may be called active absorption, and includes the operations of the lacteals and lymphatics. As our purpose is surgical and not physiological, we cannot enter at length into the nature of their functions, or into the various disputations of which those functions have been the subject. Suffice it to say, that whilst every part of the alimentary canal

has the power of absorbing some nutritive liquids—soup and wine for example, may be absorbed by mouth and rectum—the lacteal vessels seem to seek and absorb some special elements; that these are important, is evident from the ill effects which ensue if they are intercepted by disease.

What precise elements they are, which the lacteals select to the exclusion of others, we know not; neither do we know the earliest steps of the process. We do not exactly know, for instance, the mechanism by which they select chyle from the contents of the intestines.

The brothers Goodsir, in their very able and interesting *Anatomical and Pathological Observations* (Edinburgh, 1845, p. 8, et seq.), state that the terminal loops of the lacteals, in the villi of the intestines, are surrounded by a crowd of minute cells; and on this fact they built up a very ingenious theory, in reference to absorption in health and disease;—in which the enthusiasm with which the new cell-doctrines were embraced, is apparent.

They believe that these cells have the power of attracting certain matters from the contents of the intestines; and that when filled they burst and discharge their contents around the looped extremities of the lacteals, by which they are absorbed.

“Not only are cells,” they say, “the germs of all the tissues, but they are also the immediate agents of secretion. A primitive cell absorbs from the blood in the capillaries, the matters necessary to enable it to form, in one set of instances, nerve, muscle, bone, if nutrition be its function; milk, bile, urine, in another set of instances, if secretion be the duty assigned to it. The only difference between the two functions being, that in the first, the cell dissolves, disappears *among the textures*, after having performed its part; in the other it dissolves, disappears, and throws out its contents *on a free surface*. Now, it will be perceived that before a cell can perform its function as a nutritive cell, or as a secreting cell, it must have acted as an absorbing cell. This absorption, too, must necessarily be of a peculiar and specific nature. It is in virtue of it, that the nutritive cell selects and absorbs from the liquor sanguinis, those parts of the latter necessary for building up the peculiar texture of which the cell is the germ. It is in virtue of this peculiar force, that the secreting cell not only detects and absorbs, but also in some instances elaborates from the same common material, the particular secretion of which it is the immediate organ. *And it is by the same force that the cell becomes the immediate agent of absorption in certain morbid processes.*”

From the foregoing passage, it will appear that the Goodsirs attributed to cells the power of absorbing materials from the intestines, which materials, by their bursting when ripe, they discharged into the interstices of the roots of the lacteals, whence absorption by the lacteals took place afterwards. They believed further, that this was not only a type of the usual office of cells in nutrition, secretion, and absorption, but that processes of diseased absorption were effected in the same way. To this last point we shall return presently—our present purpose is with the function of the lacteals and lymphatics, so far as they illustrate any part of surgical pathology.

Whatever may be the interpretation of the origin of the lacteal vessels, the nature of the

lacteal and lymphatic glands is a perfect mystery. These consist of masses of nucleated cells, either disposed within or around (it is not certain which) a mesh of lacteal or lymphatic vessels. That they are often the seats of inflammatory exudation, in certain individuals when there is any injury, abrasion, ulceration, or other cachectic process at any part whence their radicles are derived, is familiar enough. What their functions are in health, what changes they produce on the liquid that filters through them, and what it is which makes them *take on* inflammation after some injuries, and not after others, are things quite inexplicable.

The lymphatic vessels (or *absorbents*) seem to have the office of absorbing everywhere any excess of liquor sanguinis which may be exuded in the process of nutrition. They may absorb, as we have just intimated, a liquid contaminated by unhealthy exudation; and such liquid may produce inflammation and abscess at any part of their course up to the nearest lymphatic ganglion, or beyond. They may also absorb, from certain morbid growths, as cancer, and epithelioma, and enchondroma, a liquid containing the germs of those growths, which may be developed at the nearest gland, but why this should be the case with some tumours and not with all, is another mystery.

Thus it will be evident, that the lymphatic vessels and glands, in their function as absorbents, present many points of interest to the surgeon. But there is one important morbid process which Hunter ascribed to their agency, which modern pathology compels us to deny, and that is *ulceration*. Not only is there not the shadow of a proof that this process is in any way or in any degree effected by the lymphatic vessels, but the eye affords the clearest evidence that it consists in the piecemeal liquefaction and destruction of the ulcerating tissue, which, before it ulcerates is most probably infiltrated with some unhealthy exudation. Ulceration is, in fact, a variety of mortification—a sloughing in detail. It ranks with other cases in which an exudation is melted down, and the tissues which are infiltrated share in the destruction. This is the case in every abscess; and this is the process by which abscesses are brought to the surface, but in this the lymphatics take no share.

We will now go on to a fifth class of cases; which may also, so far as proved, be considered cases of active absorption, and which may be comprehended under the idea, that rapidly growing cells may take into themselves the solid and liquid substances surrounding them, and grow at their expense. The facts of this class of cases and the history of the opinions which have been founded thereon, may be shortly expressed thus:—

During the Hunterian era of modern surgery, every morbid process was spoken of as an *action* of the parts concerned, and more especially of their vessels; for the fact was overlooked that many most important steps in organisation occur long previous to the appearance either of blood or blood-vessels. British surgeons considered it orthodox to state that it was the *action of the vessels* which was the cause of all growth, all secretion, and all disease; and in particular, as we have repeated in this article, all absorption, wasting, and ulceration whatever, were assumed to be the work of the lymphatic vessels.

In 1833, the established doctrines respecting ulceration received a rude shock from Mr. Aston

Key (*Med. Chir. Trans.* vols. xviii. xix.), who asserted his belief that ulceration in general was a process of liquefaction, or disintegration, or disorganisation of the ulcerating tissue;—"a process," he calls it, "analogous to the softening attending suppuration; it is a degeneration of tissue; a change in the affinities existing between its component parts, by which it becomes changed from a solid texture into a fluid inorganic mass." But in addition to this form of ulceration, he described another, by which he believed bone and cartilage to be more frequently affected. And this other form of ulceration consists in this; in the existence of an *absorbing tissue* which grows upon and eats into the cartilage. This absorbing tissue, in some cases of ulceration of cartilage, he believed to be produced by a transformation of the synovial membrane, in other cases, to be developed as a fresh morbid production of the scrofulous order, from the articular extremity of the bone. We cannot here enter into any details on the subject of ulceration of cartilage, suffice it to say, that Key looked upon that pulpy and gelatinous membrane so often developed on the surface of diseased cartilages, and apparently fitting into every groove and inequality of the surface, as the agent by which their absorption was effected. In the same manner he believed bone to be absorbed by the agency of granulations, and ligament likewise.

"In ligamentous fibre," he says, "the process of ulceration appears to be accompanied with some peculiar circumstances. The ligament, instead of preserving its usual form and size, becomes distended and feels pulpy. When cut into, the fibres are found to be separated from each other by a vascular structure, which upon being injected, has a villous appearance. * * It is not improbable that the ligamentous fibres themselves are passive in the ulcerative process, which there is some reason for believing is performed entirely by the vascular tissue that surrounds them."

Thus far then, we have seen Mr. Key maintaining that one tissue can be absorbed by another actively growing tissue, on its surface, or in its interstices. This idea was attempted by the Goodsirs to be elaborated into a general law; applicable not only to the absorption of chyle by the lacteals (which we have already spoken of) but also to many other cases, including the absorption of nourishment by the placenta and including ulceration.

An ulcer, according to the Goodsirs, is not a chasm formed by the action of the absorbents, as Hunter said; nor yet resulting from the liquefaction and disintegration *pure et simple* of the diseased structure; but a chasm resulting from the action of a peculiar cell growth, which, as they allege, covers its surface, and grows at the expense of the tissue which it covers, and then immediately decays and disappears.

This view of ulceration, presents the strongest analogy to the growth of *dry rot*, and of other destructive fungi upon or within the substance of wood or stone; producing speedy ruin by first living upon the textures they invade, and then perishing themselves.

That it is probable that some tissues do actually disappear in this manner is shown by what takes place in the absorption of bone and teeth. This process was described as to all essential points, by the Goodsirs in their essays before quoted; but it was afterwards more fully detailed by Mr. Tomes

and Mr. Campbell De Morgan, in a paper "*On the Structure and Development of Bone*," which was published in the *Philosophical Transactions* for 1853.

In the first place, these gentlemen show the well-known fact, that the solid block of cartilage, which is laid down as the precursor and substratum of bone, soon becomes tunnelled out into canals (called Haversian canals or spaces), in order to permit of the access of blood-vessels previous to the conversion of cartilage into bone. For, as we need scarcely say, whilst cartilage is non-vascular, true bone is always abundantly supplied with red blood.

In the next place they show that bone, once fully formed, is by no means a permanent substance, but that it is subject to incessant absorption and renewal. A section of a long bone displays the bony tissue arranged in concentric rings around the blood-vessels which occupy the Haversian spaces. But it is evident on inspection, that the Haversian systems of rings are by no means universally perfect and regular; on the contrary, they display a multitude of irregular patches of laminae, looking like disjointed and *unconformable* patches of strata in a geological section, and testifying to the fact, that just as cartilage originally is tunnelled out for the formation of the first blood-vessels, and of the concentric rings of bone which are formed around those blood-vessels, so bone itself is incessantly undergoing a similar process. New longitudinal channels are continually being excavated, and continually being filled up with new bone; so that this tissue undergoes day by day change of material, the old portions being removed interstitially and new deposited.

As to the mechanism by which this absorption of bone is effected, the opinions of Mr. Tomes and Mr. De Morgan are almost identical with those of the Goodsirs. They believe that an active cell growth is the agent by which the bone is absorbed and passed into the circulating fluid, both normally in the healthy processes of absorption and nutritive renewal, and in disease. And they believe that it is by means of a similar cell growth that the fangs of the milk teeth are absorbed.

"When a portion of dead or dying bone," says Mr. Goodsir, "is about to be separated from the living, the process which occurs is essentially the same as that which has been described. The Haversian canals which immediately bound the dead or dying bone are enlarged contemporaneously with the filling of their cavities with a cellular growth. As this proceeds contiguous canals are thrown into one another. At last the dead or dying bone is connected to the living by the cellular mass alone. It is now loose, and has become so in consequence of the cellular layer which surrounds it presenting a free surface and throwing off pus."

In the same manner Messrs. Tomes and De Morgan describe the hollowing out of the medullary cavity of the end of a femur—exposed in a stump,—by a dense pale pink tissue, consisting of nucleated cells; which evidently increased as the bone decreased. "The cellular mass," they say, "was tolerably vascular, but the vessels did not reach the surface in contact with the bone; hence they could not be regarded as having any immediate action in the process of absorption."

"If," they continue, "we examine the fangs

of temporary teeth when they are undergoing removal, similar states to those described in the portion of femur will be found to obtain. A similar cellular mass will be found closely applied to that surface of the tooth which is in process of removal." "It is difficult to resist the belief that the cells which lie in contact with wasting bone and dentine take up those tissues and use all or part of them for their own increase and multiplication, or else form a medium through which they are passed into the circulation."

These gentlemen believe that ivory pegs, such as are sometimes driven into bone, to excite the reparative processes of the fracture, may be absorbed by the cell growths of the Haversian spaces of the bone around. (See *Macartney, on Inflammation*, p. 46; and an article on *Bone*, in *Brit. and For. Med. Rev.* by R. Drutt, July, 1854.)

Now let us sum up the various facts and doctrines which relate to this, our fifth category of cases of absorption. It is alleged, as a sort of general law, that rapidly growing cells may absorb tissues with which they are in contact. Leaving out of question the supposed cell growths in the villi of the intestines, and in the lacteal and lymphatic glands, we find the facts brought forward in proof of the doctrine to be first, a supposed layer of cells on the surface of all ulcers. But this is purely hypothetical, and has never been demonstrated, and may be dismissed without further comment.

Secondly, there is the false membrane on the surface of cartilage, which was supposed by Key and Goodsir to erode that structure in ulceration. But it has been fully shown by Redfern that the changes in cartilage are intrinsic and original, and not mere consequence of the action of any membrane applied to the surface.

There remains then only the case of bone and teeth, in which it certainly is highly probable, if not proved to demonstration, that absorption in health and disease, for nutrition and for destruction, is effected by means of a cell growth.

But then it must be remarked, that the cells which absorb bone and tooth, do not appear to be invested with that function specially. On the contrary, the same cell growth which begins by tunnelling out a new Haversian space in bone, ends by being converted into new bone, to fill up the very void it had created. And the vascular growth which absorbs the fang of a milk tooth, when that tooth has dropped out, grows up to the level of the gum, becomes invested with epithelium, drops its absorbent function, and comports itself like ordinary gum.

Moreover it must be observed, that absorption is not the function of all rapidly increasing cell growths in contact with teeth, as, for example, in epulis the fangs of the teeth are not absorbed.

The writer has often made investigations of muscle infiltrated with cancer, to see whether in this case of a most vigorous cell growth intruding into another tissue, anything like absorption, such as that of bone under similar circumstances, could be detected. But it could not. In the case of a heart which presented several nodules of cancerous deposit, abruptly defined, it appeared as if the muscular fibres infiltrated with the new growth were gradually starved, atrophied, decolorised, and degenerate, but not as if they were

for a long time bodily *absorbed* by the new growth.

There is yet another class of absorption ; that which Hunter called the *progressive* ; such as happens when the sternum or vertebræ perish before the progress of an aneurism. Why the presence of a growing tumour adjacent to a bone should cause it to waste, we cannot at present explain.

In the foregoing columns we have attempted a rapid review of all the various processes which have been formerly, or are now, denominated by the term absorption. We have seen that these processes are most various. There is the introduction of foreign matter into the blood ; either as food or poison, whether specially through the lacteals or by imbibition of surfaces in general. There is the wasting of natural tissues, general or local, when nutrition is impeded either from natural causes, or from disease. There is the removal of morbid exudations and deposits. And to these instances, for some of which absorption is not a proper name, as not expressing the prominent condition concerned, there has been added ulceration, which has no title to the term absorption at all. We have also seen that, even in the instances which may pass under that term, the vessels called absorbent, are really not concerned, for the most part.

Now let us speak of the second branch of our subject, and give such particulars respecting the introduction of foreign matters into the veins as may interest the surgeon.

When there is any difficulty of swallowing, or of digesting food when swallowed, it is expedient to inject nourishing fluids into the rectum, or even to bathe the hands and feet with them, that they may be absorbed from thence. It is often desirable also, to introduce narcotic, or saline, or acid, or alkaline remedies, or mercury through the skin or bowels. The general principles with which the surgeon should be acquainted, seem briefly to be these : —

The first point is to cause the liquid, (or substance which is to be absorbed,) to be imbibed by the surface it is presented to. Now, there is no liquid from which the animal tissues universally have so much attraction as they have for water. This universal solvent forms by far the greater portion of their weight, and is imbibed with facility by them all ; whilst saline solutions of all kinds are imbibed far less readily. It follows, therefore, as a general rule, that the more diluted solutions are the better. Alcohol, ether, oils and most other liquids, are imbibed to a certain degree ; but not acids or corrosive solutions, strong enough to decompose the skin, and to coagulate the blood in the veins. If a narcotic substance is intended to be absorbed by the skin, it should be combined with a liquid which will not easily evaporate and so leave it dry, in which state it can scarcely be absorbed at all. For this reason glycerine is a better menstruum than either water or alcohol for liniments of belladonna, opium, and the like. If the matter to be imbibed is a semi-liquid, as the mercurial ointment, friction is of use in forcing it through the cuticle.

Nor must it be forgotten, that the cuticle is, as it were, an organic varnish ; a layer of scales, specially designed by nature to limit the transmission of liquids, whether from within or from without.

We need not recall to the memory of the surgeon how soon a subject for dissection dries up if the cuticle be removed ; and it is equally certain that the penetration of all substances into the tissues is greatly promoted if the cuticle be removed. Hence, many substances which may be applied to the unbroken cuticle with safety, would be most dangerous if applied to a blistered surface, from the greater completeness and rapidity of their absorption ; and the surgeon may often avail himself of very small blisters, in order to introduce morphia, or other narcotics near any painful part. Such medicines have also been introduced by inoculation or puncture ; or even by injection of solutions into the areolar tissue ; but these latter processes are painful and not often employed.

When the material to be absorbed has penetrated the tissues, the next object is, that it should enter the blood-vessels, and be carried away as rapidly as possible by the current of blood. This it is after all which is the truly efficient instrument of absorption, for the blood continually passing, carries off whatever is imbibed by the coats of the blood-vessels, and so keeps up a constant current towards itself. It must be evident, therefore, that everything which renders the circulation rapid promotes absorption ; whilst everything which causes stagnation of blood has the contrary effect. Thus if the physical qualities of the material which is desired to be absorbed are such as to produce a *stasis* in the blood, as, for example, when saline or metallic solutions are used in too concentrated a form, and more especially if they are such as to cause coagulation, absorption will be greatly hindered. The density of saline solutions should theoretically be less than that of the liquor sanguinis. (*Liebig, on the Motion of the Juices*, Lond. 1848.)

It appears that the more empty the blood-vessels the more easily they absorb ; whilst filling them even with warm water, as was done by Majendie, impedes absorption.

Some attention is expedient to the channels by which any given substance may be eliminated. Thus if it be deemed advisable to impregnate the blood with mercury, it should be introduced through the skin, or mucous membrane of the fauces, rather than through the stomach, from which it would pass to the liver and bowels, organs by which the elimination of the metal is most easily effected.

The principles on which the absorption of deleterious matters may be hindered, will be readily seen from what has gone before. Suppose any poison to have come into contact with the abraded cutis, the application of some powerful cauterant, as the nitric acid, nitrate of silver, or of mercury, actual cautery, alcohol, turpentine, &c., even if not capable of decomposing the poison before it is imbibed by the vessels, will produce a local inflammation, with stagnation of blood, and exudation, which will be unfavourable to absorption. The mode in which ligatures, exhausted cupping glasses, and suction of all sorts hinders absorption must be obvious.

It may be noticed too, that in cases in which there is a liability to infection from liquid or gaseous animal poisons ; for instance, in the case of surgeons who dress erysipelatous wounds, or have to breathe a tainted atmosphere, the maintenance of a high state of health by good diet,

stimulants, and exercise, if it does not render the veins less liable to imbibe a poison, will render the blood far less liable to be influenced by it.

In reference also to preventing the absorption of erysipelatous miasm by wounds and abrasions, we may point to the expediency of sealing up such injuries from the contact of hospital air, by means of Friar's balsam, collodion, or solution of the chloride of iron; which are far better adapted as applications to wounds, under such circumstances, than water dressing and other moist applications.

We now approach the third and last part of our subject, which is the consideration of the principles by which the surgeon is guided when he desires to promote the absorption of morbid exudations of various kinds, solid or liquid. Here we may claim the indulgence of our readers for the slightness of the sketch which we are able to give; but it must be remembered that almost half of the practice of physic is involved in these principles.

The exudations of which the surgeon may desire to promote the absorption may be of infinite variety;—pure blood; some of the elements of blood, either healthy, or combined with, as we may assume, various noxious substances, or in various states of decomposition; as the serum, fibrine, and pus, which are the products of various forms of inflammation:—again, they may consist of blood elements which have been developed into areolar tissue, or into bone, in consequence of common inflammation;—or of the various adventitious growths, which result from certain conditions of the blood, such as tubercular deposits, so called;—the bony and cartilaginous enlargements of gout, rheumatism, or syphilis:—the whole catalogue of tumours, fibroplastic, glandular, enchondromatous, epithelial, and cancerous; growths too, which come under the term hypertrophies, and tumours of which it is doubtful whether they result from some blood taint or some error in the original scheme of growth, such as wens, nævus, and the like. This list is tolerably extensive; but we desire to bring before the mind at one view, all the cases in which absorption of exudation in any stage of development is desirable. As we have said, it is general principles only that can be treated of here: details will be found in other articles.

In this matter, three things have to be considered:—1. The state of the blood; 2. the state of the exudation as to development and vitality, or the capacity therefor; 3. the state of the parts in which the exudation is situated.

The first point is, in most cases, the one important thing, as is shown more at length in the article INFLAMMATION. Take exudations as a whole, and it will be found that by far the greater number vanish spontaneously, so soon as the blood is purified from the particular element which was the cause of the mischief.

But, in the second place, the condition of the exudation must be regarded. Some there are, which are in such a state from decomposition, that their absorption into the blood would scarcely be desirable if possible. Such are the fluids exuded in carbuncle and unhealthy suppurations, or in which pus has become putrid from admixture with secretions of the bowels, or with urine. For such cases, free evacuation and not absorption is the thing to be desired.

Some matters there are too, of which the absorption would seem to be clearly against nature.

For example, cutaneous cysts filled with epithelium, and commonly called wens, can by no known means be made to absorb their contents; and it would seem manifestly contrary to reason to expect that excrementitious substances, such as cuticle and sebaceous matter should be taken into the blood again by the very organ whose function it is to eliminate them.

Dismissing then these cases, we have to pass in review the far more difficult and complex cases in which it is sought to cause the absorption of exudations which have acquired some degree of development, and have, as it were, made good their footing in the animal economy, and which persist, even though the condition of blood which originally caused them has ceased; or which when once existing have the power of propagating themselves and keeping up a blood infection.

It is certain that the organic elements, of which some parts of the body are composed, are not endowed with more than very transitory powers of life. Hair, cuticle, epithelium, and gland cells are incessantly being shed and renewed. The vital history of the milk teeth is obvious. What the processes of removal and renewal are in bone, we have learned from the before-quoted researches of Mr. Tomes and Mr. De Morgan. And it is *probable* that the other portions of the framework of the body, including skin, areolar tissue, ligament, basement membrane and sarcolemma of muscle are also subject to similar renewal, although the fact has never been demonstrated so completely as it has been with respect to bone. We speak here of the more inert portions of the body: not of active parts, such as muscle, whose rapid solution and replacement is morally certain. But regarding the time which any portion of the skin or ligament ought normally to last, before it is renewed, we know nothing. Beyond the *general* fact, too, that abundant nourishment and a brisk circulation are favourable to the maintenance of all tissues, and the converse, we know little, if anything, of *special* means for promoting the growth or the decay of any tissue. We can, by starving the whole body, or by robbing the food of essential nutritive elements, cause a general waste of fat, areolar tissue, muscle, and bone. We know further, that in cases of insufficient nourishment or mal-assimilation, some tissues are prone to degeneration: in one patient the hair falls, in another the teeth decay, in a third the nails cease to be regularly secreted, in another the callus uniting a fracture may disappear, in another the cornea or articular cartilages will ulcerate; but we know little of special means of effecting the increase or decay of any tissue in particular, beyond the general one of increasing or decreasing the supply of food, and the general waste by exercise, air, and excretion. We have no special means, besides, by which we can promote the growth, or cause decay specially, of hair, cuticle, bone, cartilage, or gland, or ligament.

The same is true with regard to adventitious and intrusive growths. We know little of the vital history of any of these; whether, for example, the mass, which is originally deposited as cancer or enchondroma, remains the same throughout its career, or whether it is subjected to a process of absorption and renewal, like normal tissues. We do not know how to eliminate the pabulum of these tumours in the blood, nor do we know what complementary substances are capable of neutralising it.

Exudations further may perish, and pass into a state of degeneration, in which they are quite harmless, and may exist during the whole of life in the interstices of tissues, but yet seem capable of very slow absorption, if any. For example, the common so-called "yellow cheesy tubercle" is a mass of decayed exudation, most generally of imperfect fibroplastic matter and epithelium in the lungs, or of some unhealthy fibrinous matter in a lymphatic gland; it is perfectly dead, and in a state of fatty or earthy degeneration, consisting of amorphous granular matter, oil globules, cholesterine, and earthy matter. Masses of this sort may remain harmlessly in the lymphatic glands for years. Portions of cancer or enchondroma, or of any other tumour may pass into the same state, undergoing the slowest possible absorption, first of the oil, then of the granular matter, and leaving a putty-like mass to the end of life.

In the third place, the state of the parts in which an exudation is situated may be an obstacle to its removal. A slow circulation generally; and of that of action of the veins in particular; relaxation and want of tone in the skin, muscles, and areolar tissues, are common causes. In acute hydrocephalus, the difficulty or impossibility of causing absorption of the effused serum are notorious; but death more probably results from the injury done to the structure of the brain, which renders absorption of the serum impossible, than from the mere presence of the serum. There are many surfaces which seem to lose the power of absorbing serous liquid, although such liquids may be readily enough taken up by the areolar tissue, as in the case of ganglion and hydrocele. In the case of cystic tumours, the mere absorption of the fluid contents of the cysts, is but a small part of the morbid conditions.

It remains for us shortly to enumerate the remedies which in various modes influence absorption, and the principles of their operation.

Air, abstinence, exercise, and purgative medicine may be said generally to promote absorption of the entire body. Copious libations of water, and diuretic medicines in general, especially the alkaline salts, have the same effects. It has been proved that both water and potass, in passing through the blood, cause an excess of solid matter to be excreted by the kidney. The solution of caustic potass is reputed to be of service in causing absorptive effect. (See TUMOURS.) The tincture of cantharides, it is said, has succeeded in removing the fluid in hydrocephalus. Amongst purgatives, the compound jalap powder and elaterium have the greatest virtue in cases of serous exudation, since they rob the blood so suddenly of large quantities of watery fluid that it more readily imbibes any serum that may be extravasated. Mercury, in its various preparations, is the medicine more universally relied on than any other for the power of causing absorption. And here it may be useful to remark, that it may be employed in two distinct modes, which should never be confounded. One is, when it is intended to abstract from the blood any redundant or morbid material, and to discharge it by means of abundant secretion from the liver. Another is, when it is intended to accumulate to a certain degree in the blood (the test of which is either slight pyalism or dysentery), and to produce, as is believed, certain changes in the condition of an exudation which shall render it more easily absorbed. These

two modes of operation, which ought always to be kept distinct in the mind of the practitioner, may yet to a certain degree be carried on together in some cases. The first, or evacuant operation, is to be effected by tolerably large doses, combined with drugs which shall cause purgation; and this is best adapted for early stages of disease, as a preventive of exudation, or to remove it soon after it is deposited. The other, or mercurial impregnation of the blood, is supposed to exert a *catalytic*, or (if we may discard the absurd use of new Greek words, which explain no more than terms already employed) a *dissolvent* action over exudations which are already undergoing development.

The cases in which this mercurial action is most beneficial are decidedly those in which there is a syphilitic taint; next, those of fibrinous interstitial deposit — thickenings of membranes, opacities of the cornea, and adhesions generally; but for inflammations of mucous membranes, erysipelatous, diphtheritic, and atonic exudations it is not adapted. (See INFLAMMATION.)

Next to mercury, the iodide of potassium is the most universal absorbefacient, especially in cases of exudation, or of bony deposit connected either with syphilitic, gouty, or rheumatic taint. Colchicum, especially the acetic extract in small doses, has considerable power over gouty exudations; and antimony over acute exudations in the lungs. Blisters and counter-irritants generally may be supposed to rob the blood, or the tissues near enough to be influenced by them, of certain elements which are abstracted from the seat of exudation. Friction and cold affusion promote a more rapid circulation, and so hasten the disappearance of exudations after the inflammatory stage has passed. Pressure operates in two ways — by preventing stagnation in the veins, and supplying the place of skin or muscle which have lost their tone, and cease to give normal support to the vessels. The leg, the scrotum, and abdomen are the parts to which pressure may be applied most beneficially with this intention. But pressure may be applied for another purpose, namely, to *starve* a tumour by limiting the supply of blood to it. Illustrations of this purpose of using pressure will be found in the articles on CANCER, TUMOURS, and OVARIAN DROPSY. To carry out the same intention most effectually, the arteries supplying a tumour are sometimes tied.

The remedies we have hitherto spoken of act by abstraction for the most part. But in the case of exudations arising from tenuity of the blood, the proper remedies are substances which supply the wanting elements, or which act complementarily to elements in excess. Hence, wine, good diet, cod-liver oil, and bark are of service in atonic effusions — and, above all, iron, which is almost a specific. The potassio-tartrate, and other combinations with diuretics, is of service at the close of inflammatory attacks that have left the lungs or other organs oedematous; the tincture of the sesquichloride, in doses of ten minims, combined with one-sixteenth of a grain of corrosive sublimate, is of great service in atonic engorgements of the womb. The corrosive sublimate, with tincture of bark, is a well-known remedy of analogous virtues.

There is one remaining mode of procuring absorption, which was idealised by Hunter when he spoke of "an action excited by irritation being incompatible with the natural actions and existence of

the parts, which therefore become ready for removal;" or, in more modern phraseology, a part may waste and be atrophied if some of the conditions requisite for its life and health be interfered with. Thus the gums, if impregnated with mercury, may waste. So the testicle may waste if deposits have taken place in it, which first of all starve the natural tissue, and then undergo atrophy themselves. Such is sometimes the result of inflammation of muscle. This process may be imitated, and tumours caused to waste by exciting inflammation or a new interstitial deposit throughout their substance, either by setons, or by stimulating or astringent injections.—[*R. Druitt.*]

ACETATE OF LEAD. See LEAD.

ACETATE OF MORPHIA. See MORPHIA.

ACETIC ACID. Strong acetic acid contains about 30 per cent. of absolute anhydrous acetic acid. The *acidum aceticum dilutum* of the present pharmacopœia contains about four and a half per cent of the same substance.

Acetum destilatum, or distilled vinegar, is of similar strength.

Distilled vinegar, mixed with farinaceous substances, is frequently applied to sprained joints, and, in conjunction with alcohol and water, makes an eligible lotion for many cases in which it is desirable to keep up an evaporation from the surface of inflamed parts. Vinegar was once considered useful in quickening exfoliations, which effect was ascribed to its property of dissolving phosphate of lime. Its good effects on burns and scalds were taken particular notice of by Mr. Cleghorn, a brewer in Edinburgh, whose observations were deemed by Mr. Hunter worthy of publication. (See *Med. Facts and Obs.* vol. ii.)

Diluted vinegar is alleged to be the best lotion for freeing the eye from any small particles of lime which happen to have fallen into, and become adherent to it, or the inside of the eye-lids. (See *A. T. Thomson's Dispensatory*, p. 8, ed. 2.)

Distilled vinegar is sometimes employed as a styptic for stopping hemorrhage from the nose. With this view, it may be used either as an injection, or a lotion, in which lint is dipped, and introduced up the nostril. It is often used to lessen the disagreeable smell of sick rooms. Strong acetic acid is a good application for the destruction of warts and corns, care being taken not to injure the surrounding skin with it. (*Brand's Manual of Pharmacy*, p. 9, 8vo. Lond. 1825.)

The pyroligneous acid, which is merely strong acetic acid impregnated with empyreumatic oil and bitumen, is commended by Mr. Buchanan, of Hull, as an ingredient in applications to the ear for the relief of certain cases of deafness. (See *Illustrations of Acoustic Surgery*, 8vo. Lond. 1825.)

ACHILLES, *Tendon of*. See TENDONS.

ACTUAL CAUTERY. See CAUTERY.

ACUPUNCTURE (from *acus*, a needle, and *pungo*, to prick). The operation of making small punctures in certain parts of the body with a needle, for the purpose of relieving diseases, as is practised in Siam, Japan, and other oriental countries, for the cure of headaches, lethargies, convulsions, colics, &c. (See *Phil. Trans.* No. 148; and *Willh. Ten. Rhyne, de Arthritide, Mantissa Schematica*, &c. 8vo. Lond. 1633.) Dr. Elliotson has tried acupuncture extensively, and his experience coincides with that of Mr. Churchill, confirming the fact that, as a remedy for chronic rheumatism,

it answers best where the disorder is seated in fleshy parts. He also finds, that one needle, allowed to remain an hour or two in the part is more efficient than several used but for a few minutes. (See *Med. Chir. Trans.* vol. xiii. p. 467.) Neuralgia is a disease in which the practice may deserve trial. Local paralysis is another. In a modern French work, it has been highly commended: but the author sets so rash an example, and is so wild in his expectations of what may be done by the thrust of a needle, that the tenor of his observations will not meet with many approvers. For instance, in one case, he ventured to pierce the epigastric region so deeply that *the coats of the stomach were supposed to have been perforated: this was done for the cure of an obstinate cough, and is alleged to have effected a cure!* But if this be not enough to excite wonder, I am sure the author's suggestion to run a long needle into the right ventricle of the heart, in cases of asphyxia, must create that sensation.

See *Berlioz, Mém. sur les Maladies Chroniques, et sur l'Acupuncture*, p. 305—309. 8vo. Paris, 1816. *Churchill on Acupuncture*, 1824; *Dantu, Traité de l'Acupuncture*, 1826.

ADHESION. A term signifying the union of opposite surfaces. This is exemplified in the union of WOUNDS, of FRACTURED BONES and of RUPTURED TENDONS, to which articles, as well as to that on REPAIR, we may refer for the history of adhesion so far as it is related to the effect of injury.

The material by which adhesion is effected is the fibrine, or coagulable lymph of the blood, which may be exuded either without inflammation in the most favourable instances of repair, or, in consequence of inflammation, which, when it stops short with the production of fibrinous exudation, and does not cause suppuration, is erroneously called the ADHESIVE INFLAMMATION. (q. v.)

The fibrine exuded either with or without inflammation is of three destinations. 1. It may be quickly absorbed (see ABSORPTION). 2. It may undergo liquefaction into pus (see SUPPURATION); or may slowly waste and degenerate into a stuff looking like putty; or, 3. It may undergo development into areolar tissue, in the form of *cicatrix*, false membrane, bands of adhesion, and so forth.—[*R. Druitt.*]

AGARIC. A species of fungus, growing on the oak, and formerly celebrated for its efficacy in stopping bleeding. (See HEMORRHAGE.)

ALBUGO (from *albus*, white). A white opacity of the cornea, not of a superficial kind, but affecting the very substance of this membrane. (See LEUCOMA.)

ALUM, *Sulphate of alumina and potash*. Ten grains of alum, made into a bolus with conserve of roses, may be given thrice a day in internal hemorrhages, gleet, leucorrhœa, and other cases demanding astringent remedies. In a relaxed state of the urinary passages, or want of power of the sphincter vesicæ, small doses of alum are said to have been of service. Alum is employed as an ingredient in many astringent lotions, gargles, injections, and collyria. (See LOTIO ALUMINIS.) Dr. Groshuis, a Dutch physician, first recommended its use in colica pictonum, and Dr. Perceval subsequently joined in the advice. The principle, on which it has been supposed to act, is that of decomposing the common preparations of lead, and converting them into sulphates, which are compa-

ratively innoxious. Burnt alum is a principal ingredient in many styptic powders.

ALVINE CONCRETIONS. See *INTESTINAL CONCRETIONS*.

AMAUROSIS (from *ἀμαυρόω*, to darken) *Gutta serena*. *Suffusio nigra*. Germ. *Schwarzer Staar*. That diminution or total loss of sight which immediately depends upon the morbid state of the retina and optic nerve, whether this morbid state exist as the only defect, or be complicated with other mischief; whether it be a primary affection, or a secondary one, induced by previous disease of other parts of the eye. (*Beer*.) All those imperfections of vision which depend upon a morbid condition, *whether affecting structure or function*, of the sentient apparatus proper to the organ. (*Travers's Synopsis of the Dis. of the Eye*, p. 293.)

Obscurity of vision depending on a morbid condition of one or several portions of the optic nerve, its root, its course, or its termination. It is an effect therefore depending upon causes entirely different from those which prevent the rays of light from entering the eye or passing through it to the retina. (*Mackenzie on Dis. of the Eye*, p. 1015, ed. 4.) Any great imperfection or loss of vision existing independently of any change in the natural transparency of the parts anterior to the retina, or of any manifest varicose enlargement of the vessels of the choroid, or of any material alteration in the configuration of the eye-ball. (*R. Middlemore on Dis. of the Eye*, vol. ii. p. 242.)

The imperfection or loss of sight, which results from affection of the nervous apparatus belonging to the eye, whether that affection be seated in the retina, the optic nerve, or the sensorium; whether it be idiopathic or primary, sympathetic or secondary: whether it consist in vascular congestion, or organic change, or simply in functional disturbance. (*Lawrence on Dis. of the Eye*, ed. 3, p. 506.)

By the expression *gutta serena*, is usually signified the complete or fully developed form of amaurosis, that in which the patient has little or no power of distinguishing light from darkness. The term took its origin in the notion which formerly prevailed that the blindness was caused by the effusion of a humour or fluid at or behind the pupil, and as the latter opening retained its natural blackness in amaurosis the effused drop was said to be clear.

Amaurosis then does not uniformly take place as a single independent disorder; but not unfrequently presents itself as a symptomatic effect of some other disease of the eye: a fact exemplified in hydrophthalmia, cirsophthalmia, glaucoma, &c. And as Mr. Wardrop observes, amaurosis, in its usual acceptation, signifies a symptom of disease, as well as a distinct affection. (*Essays on the Morbid Anatomy of the Human Eye*, vol. ii. p. 165, 8vo. Lond. 1818.) With respect to the mere name of the kind of disease here implied by amaurosis its correctness will remain the same, whether the iris be moveable or immoveable; whether the pupil be preternaturally enlarged, or contracted, and whether it be perfectly clear and transparent, or more or less turbid; for the name only refers to the morbid state of the retina and optic nerve, and not to the condition of the sight in general. When the long established name of *amaurosis* is received with this precise meaning, there will be not the slightest danger of confounding the disease with other affections of the eye. However, when it is

wished to make out the different forms and kinds of amaurosis, the appearances of the iris and pupil are considerations of great importance. (See *Beer's Lehre von den Augenkrankheiten*, b. ii. p. 420, &c. Wien, 1817.)

Amaurosis does not constantly attack both eyes at the same time; frequently one is attacked some time after the other, and it is not unusual even for one eye to remain sound during life, while the other is completely blind. This depends, in part upon the disposition to the disease in one eye being quite local, and in part upon the causes giving rise to the complaint extending their operation only to the eye affected. Where, also, the origin of amaurosis seems to depend altogether upon constitutional causes, one eye is not unfrequently attacked much sooner than the other; though in these examples it is more rare to find the eye which does not suffer at first continue perfectly unaffected. (*Beer*, b. ii. p. 422.)

Mr. Middlemore represents amaurosis as commonly attacking one eye first, and not commencing in the other until vision in the one first attacked is either much impaired or totally destroyed. "It is (says he) by no means an usual occurrence for amaurosis to take place in each eye at the same time, and to advance in both with an equal progress." Still, he admits, that this matter will be mainly determined by the nature of the cause producing the amaurotic affection. (*On Dis. of the Eye*, vol. ii. p. 251.) Indeed, since amaurosis may arise from affections of the sensorium, optic nerve, or retina, we can understand how it happens that it sometimes appears in both eyes at once; that it may be confined to one, or that, having taken place in one it may in the other also, after a longer or shorter interval. (*Lawrence*, op. cit. p. 507.)

Amaurosis may not completely hinder vision, a diminished power of seeing often remaining during life. Hence the division of cases into *perfect* and *imperfect*; which latter, however, sometimes attain a degree in which the patient is only just able to distinguish light, the direction of its rays, and its degree.

Amaurosis may take place in an instant, even so as to be attended with entire blindness; or it may come on quickly, that is, it may be complete in a few days or weeks; or, lastly, what is most frequently the case, it may be produced gradually, and several years elapse before it attains its utmost degree; circumstances of great moment in the diagnosis and treatment.

The type, which the disease assumes in its course and development, is also subject to great variety, and claims the utmost attention; for amaurosis may either be *permanent* or *temporary*. It is sometimes *intermittent*, making its appearance at regular or irregular intervals. In certain examples, it prevails at particular times, commonly all day, till a certain hour; or from one day till the next; or at a stated time every month.

Sometimes it is plainly a symptom of a confirmed ague, the patient being attacked with an ordinary intermittent, and blind during each paroxysm, but always regaining his sight as soon as each fit is over.

Sometimes the frequently recurring form of the disease confines itself to no determinate type; and, on account of its irregularity, it is then termed by Beer, *Amaurosis Vaga*, which, he says, is principally met with in persons liable to hysteria, hypo-

chondriasis, convulsions, or epilepsy. Periodical amaurosis, after remaining uncured a certain time, often becomes *permanent*. (Beer, *Lehre*, &c. b. ii. p. 429.)

Day-blindness (*Cæcitas Diurna*; *Nyctalopia*) and *night blindness* (*Cæcitas Crepuscularis*; *Hemeralopia*) are nothing more than cases of periodical amaurosis.

Genuine uncomplicated amaurosis, consisting of a mere diminution or loss of sight, without the appearance of any other defect, is one of the most uncommon forms of the complaint. In it, merely the vital properties of the optic nerve and retina are affected, and, after death, nothing preternatural can be traced in these parts.

This simple unmixed form of amaurosis is subdivided by Beer into that amaurotic weakness of sight, or blindness, which depends upon the sensibility of the optic nerve and retina being too highly raised, and into another case, the proximate cause of which is peculiarly and entirely referrible to depression of such sensibility. The first example is much less common than the second. Mr. Lawrence conceives, however, that they who divide amaurosis into two kinds, *that with increased*, and *that with diminished sensibility of the retina*, enumerate as symptoms of the former various kinds of impaired vision, some of which rather denote the period of excitement in disease of the retina, than the more advanced stage, ordinarily designated as amaurosis. (*On Dis. of the Eye*, ed. 3, p. 525.)

With reference to some amaurotic patients, who are annoyed by the bright light of day, Mr. Middlemore also observes, that it would seem as if the sensibility of the retina were increased, although the power of vision is greatly diminished; but, he adds, this is usually nothing more than an early symptom of only some few varieties of amaurosis; it does not continue so as to constitute one of its latter symptoms. (*On Dis. of the Eye*, vol. ii. p. 257.)

Amaurosis, then, either occurs in the form of a simple uncomplicated affection as we have described it above, or, which is more frequently the case, the disease is co-existent with other diseased appearances either in the eye, its vicinity, or some other organs at a distance from the eye, or in the general constitution. These appearances merit the most earnest consideration, because they are for the most part connected with the *cause* of amaurosis. According to this statement, then, there is a *genuine local amaurosis*, and a *complicated amaurosis*, which last may be either *local* or *general*, or of both descriptions together, and therefore named by Beer, *perfectly complicated*. (Vol. cit. p. 431.)

To the local complications, says Beer, belong cataract; glaucoma; a general varicose state of the eyeball (*cirsophthalmia*); exophthalmia; atrophy of the eye; spasms in the organ and surrounding parts; paralysis of one or more muscles of the eye (*ophthalmoplegia*); paralysis of the eyelids; ophthalmia in general, and internal ophthalmia in particular; a scorbutic bloodshot appearance of the eye (*Hyperæmia Scorbuticum*); and, finally, wounds or contusions of the eye, or adjacent parts. With these cases should also be mentioned that important disease, fungus hæmatodes of the eye. From this simple enumeration of local complications, one may see how frequently amaurosis is only a symptomatic effect of another disorder of the eye, with which it is conjoined, and how often it is con-

nected with the same common causes, which pertain to another or several other diseases of the eye.

Amongst the general complications, Beer enumerates those which are purely nervous: impairment of the health in various forms by infection, contagion, or miasmata; a bad habit of body; typhoid fevers, the amaurotic effect of which upon the eye the author of this work has frequently noticed; asthma; hydrocephalus; organic defects of the abdominal viscera; worms; chlorosis; consumption; old ulcers of the legs; organic disease of the brain and skull; complaints arising from pregnancy; hemorrhage, &c. In these general complications, the casual connection between amaurosis and some remote disease of another organ, or of the whole constitution, cannot be mistaken; and we often see the disease of some other part distant from the eye suddenly or gradually diminish, and immediately appear again as a sympathetic action in the form of amaurosis, of which the most remarkable instance presents itself after the sudden healing of old ulcers of the legs. (Beer, *Lehre von den Augenkr.* b. ii. p. 433.)

Mr. Travers divides amaurotic affections into two classes, the *organic* and the *functional*. The first comprehends alterations, however induced, in the texture or position of the retina, optic nerve, or thalamus. The second includes suspension or loss of function of the retina and optic organ, depending upon a change either in the action of the vessels, or in the tone of the sentient apparatus.

As causes of *organic* amaurosis, this author enumerates: 1. Lesion, extravasation of blood, inflammatory deposition upon either of its surfaces, and loss of transparency of the retina. 2. Morbid growths within the eyeball, dropsy, atrophy, and all such disorganisations as directly press upon, or derange the texture of the retina. 3. Apoplexy, hydrocephalus, tumours or abscesses in the brain, or in or upon the optic nerve or its sheath, and thickening, atrophy, absorption, or ossification of the latter. As causes of *functional* amaurosis, Mr. Travers specifies: 1. Temporary determination; vascular congestion, or vacuity, as from visceral or cerebral irritation; suppressed, or deranged, or excessive secretions, as of the liver, kidneys, uterus, mammæ, and testes; various forms of injury and disease; and hidden translations of remote morbid actions. 2. Paralysis idiopathica, suspension or exhaustion of sensorial power from various constitutional and local causes; from undue excitement or exertion of the visual faculty; and from the deleterious action of poisons on the nervous system, as lead, mercury, &c. From this description, says Mr. Travers, it will be understood, that organic and many forms of functional amaurosis are incurable; and the functional, by continuance, lapses into the organic disease.

Functional amaurosis is subdivided by Mr. Travers into, 1st, the *Symptomatic*, or that which is only a symptom of some general disease, or disorder of the system; as, for example, plethora, or debility: 2ndly, the *Metastatic*, or that produced by the sudden translation of the morbid action from another organ of the body; as, for example, from the skin, the testicle, &c. 3rdly, the *Proper*, or that which depends upon a peculiar condition of the retina; as, for example, the visus nebulosus, muscæ volitantes. (*Synopsis*, p. 139—155.)

Mr. Lawrence does not consider the expression *functional* amaurosis to be of any practical utility;

he argues that the exact limits of the changes termed organic have not yet been determined. "We apply the epithet functional to those diseases which produce no changes recognisable after death. But we cannot infer from these cases that no alteration had existed during life. The state of an organ, necessary to the correct execution of its function is a living, not a dead condition; it requires, not merely a certain organisation as we find after death, but a supply of healthy blood in a certain quantity, a natural state of nervous influence and sympathy, and perhaps other circumstances, not clearly understood. If all these conditions are combined, can we consider it possible, that the function should be disordered, or interrupted? If one or more should be altered, or wanting, can the disease be properly regarded as simply functional? Vascular congestion is an obvious deviation from the normal state of a part. If the retina, or any other organ, be said to be functionally disordered when its vessels appear twice as numerous and large as in the normal condition, the expression must be employed too loosely to convey any clear information." (*On Diseases of the Eye*, ed. 3, p. 508.)

It seems to Dr. Mackenzie, that amaurosis always results from an *organic cause*. The notion of a *functional* amaurosis, he conceives, must have arisen from the facts, that this disease is sometimes sympathetic, or arises in consequence of derangement of some remote organ; and that it is occasionally sudden in its attack, and, on the other hand, instantaneous in its departure. In sympathetic amaurosis, Dr. Mackenzie considers it as indisputable, that the loss of sight must depend on some organic change in the optic apparatus. Take, for example (says he), the amaurosis which arises from the presence of worms in the bowels. This result is only occasional; the brain of perhaps not more than one out of a hundred affected with worms, is so susceptible of disease, that the irritation communicated to it from the bowels, through the great sympathetic nerve, is sufficient to excite it to that morbid condition which causes dilatation of the pupils and loss of vision; but that the amaurosis, in these cases, is the consequence of any thing else than a certain morbid condition of the optic apparatus, seems to Dr. Mackenzie a proposition which scarcely deserves a serious refutation. Neither does he admit, when amaurosis occurs suddenly as a disease of relation, that it is independent of organic derangement in the optic apparatus, however indubitable it may be, that the first link in the chain of causes has existed in some remote part of the body. (*On Diseases of the Eye*, ed. 4, p. 1019.) After all, however, with the qualifications and particulars annexed by Mr. Travers to his definition of the varieties of functional amaurosis, I see a perfect agreement between him and Mr. Lawrence in the pathological view of the subject: and the only question relates to the propriety of applying the term functional to particular forms of amaurosis. The least objectionable divisions of the amauroses seem to the latter surgeon to be three, according as the disease proceeds from *affection of the sensorium*, or of *the optic nerve*, or of *the retina*; though he acknowledges, that the evidence during life leaves us sometimes in doubt, whether the case ought to be referred to one or another of these heads. Amaurosis (says he) may be induced by causes acting immediately on

the nervous apparatus of the eye, such as excessive exertion of the organ, or a stroke of lightning; it may arise secondarily from sympathy between the nervous structure of the eye and some other previously affected organ, as from irritation of the stomach, or of the nerve of the fifth pair; or it may be a symptom of affection of the sensorium, more or less general. Hence, the distinction of the complaint into *idiopathic*, *sympathetic*, and *symptomatic*. (See *Lawrence on Dis. of the Eye*, ed. 3, p. 510.)

SYMPTOMS OF AMAUROSIS.

One may consider as the only really inseparable symptom of amaurosis, that weakness of sight (*Amblyopia*), or that complete blindness, in which neither with the unassisted nor assisted eye the least defect can be perceived in the structure and shape of the affected organ. But how rarely this essential symptom is met with alone, and how frequently it is obscured by some other defect in the structure and form of the eye, is proved by daily experience.

Imperfect amaurosis, besides being characterised by considerable weakness of sight approaching to actual blindness, is mostly complicated with other morbid derangements of the visual function. Amongst the most important of these is a defective interrupted vision. (*Visus interruptus*.) For instance, when the patient is reading, single syllables, words, or lines cannot be seen, unless the eye be first directed to them by a movement of the whole head, and greater or lesser portions of other objects are in the same manner indistinguishable. Sometimes amaurotic patients can see only the upper or lower, or the left or the right half, of objects. (*Visus dimidiatus*; *Amaurosis dimidiata*; *Hemiopia*; *Hemiopsia*.) Or, when the patient shuts one eye, he can only distinguish the halves of objects; but, if he open both eyes, he sees everything in its natural form. In this case one eye is sound, and only some fibres of the nerve of sight are injured in the other. (See *Schmucker's Vermischte Chir. Schrift*, b. ii. p. 12.)

In some not very uncommon cases of imperfect amaurosis, the patient cannot see an object unless it be held in a particular direction before the eye; but, when the eye or head is moved in the least, he loses all view of the thing, and cannot easily get sight of it again. (*Beer, Lehre von den Augenkrankheiten*, b. ii. p. 424.) Patients who may be said to be entirely blind, sometimes have a small part of the retina which is still susceptible of the impression of light, and is usually situated towards one side of the eye. This obliquity of sight was long ago pointed out by the late Mr. Hey, as common in the present disease. (See *Med. Obs. and Inquiries*, vol. v.) Richter mentions, that in one man, who was, in other respects, entirely bereft of vision, this sensible point of the retina was situated obliquely over the nose, and so small, that it was always a considerable time before its situation could be discovered: he adds, that it was so sensible, as not only to discern the light, but even the spire of a distant steeple. The centre of the eye seems to be first and most seriously affected. Hence, the generality of patients, in the early stage of imperfect amaurosis, see objects which are laterally situated better than such as are immediately before them. (*Anfangsgr. der Wundarzn.*, b. iii. kap. 14.)

One of the most common symptoms of incipient amaurosis, is an appearance in the patient's fancy, as if gnats or flies were flying about before his eyes. (*Visus Muscarum, Myodesopsia.*) Sometimes transparent, dark-streaked, circular, or serpentine diminutive bodies appear as if flying in greater or lesser numbers before the eyes, often suddenly ascending, and as quickly falling down again, and chiefly annoying the patient and confusing his sight when he looks at strongly illuminated or white objects. The substances, thus appearing to fly about before the patient's eyes, are termed *Muscae volitantes; Mouches volantes.* (Beer, *Lehre, &c.* b. ii. p. 424.) If what obstructs the sight be a single black speck, it receives the name of *scotoma*.

Sometimes the muscae are not moveable, but fixed and constant in their position, in which case they will indicate that certain definite portions of the retina have become insensible to light, while the floating or moveable muscae are merely symptomatic and form no part of the disease itself.

This illusive perception of various substances being in rapid motion before the eye, gradually increases; the substances themselves become less and less transparent, and, at length, are so connected together that they form a kind of network, or gauze, by which all objects are more or less obscured. This is another symptom of amaurosis, technically called *visus reticulatus*. The network commonly has the peculiarity of being black in very light situations, or when white substances are before the eye; while, in dark places, it is quite shining, and, as it were, of a bluish white hue, like silver, though sometimes of a red-yellow, golden colour.

Sometimes, in the early stage of amaurosis, all objects seem covered with a dense mist (*visus nebulosus*), and this mist may appear for a day or two of a light gray colour, and then for another day or two very black, everything appearing as if looked at through a dense sooty smoke. (Beer, *Lehre von den Augenkrankheiten*, b. ii. pp. 422—426.)

A not uncommon symptom of imperfect amaurosis is the patient's seeing every object indistinctly in a rainbow-like, sometimes tremulous, and generally very dazzling light; while, in the dark especially, blue or yellow flashes, or fiery balls seem suddenly to pass before his eyes when the eyelids are shut, and excite considerable alarm. (*Visus lucidus; Marmoryge Hippocratis; Photopsia.*)

To an eye affected with imperfect amaurosis, all objects frequently appear indistinct, but double. (*Visus duplicatus; Diplopia.*) When the disease comes on gradually, the patient sometimes sees double, with both eyes.

In other cases, double vision only occurs when the patient looks at objects with both eyes, and it ceases as soon as he shuts either the diseased or the sound eye. In the last of these circumstances, double vision originates from the deviation of the unsound eye from the axis of sight; but, in the first instance, it arises from the morbid state of the retina itself of the diseased eye. A degree of squinting, *strabismus*, therefore, is a common symptom of incipient amaurosis, particularly when only one eye is affected; for this always deviates more or less from the axis of vision. It is owing to this loss of correspondence, that persons affected with an imperfect amaurosis of one eye, often mis-

take the relative distance of objects, and frequently see them reflected. (*Travers's Synopsis*, p. 170.)

Beer has often met with patients labouring under imperfect amaurosis, who could plainly distinguish all objects which were not very small; but saw them of a different colour from their real one; for instance, yellow, green, purple, &c. (*Visus coloratus, chrupsia.*) He had under his care an amaurotic woman, who at mid-day could discern even the smallest objects in a strong light, but they all appeared yellow, though no marks of jaundice were perceptible.

Sometimes in the early stage of amaurosis, all objects appear distorted, bent, shortened, and, in rarer instances, inverted. (*Visus disfiguratus; Metamorphosia.*) Thus the flame of a candle appears very long, but all awry. This is said by Beer to be constantly an unfavourable omen, as the cause of it lies in the brain itself.

Imperfect amaurosis is sometimes attended with considerable shortsightedness (*Myopia*), and sometimes with the opposite affection (*Presbyopia*).

Many patients, when first attacked with amaurosis, everywhere testify a partiality to a great quantity of light, employing several candles at night, and sitting in the day-time with their backs against a sunshiny window, in order to let whatever they are reading have a very strong light upon it. In some cases, however, the sensibility of the retina may be so augmented, that the patient shuns all light places, particularly those in which the light is strongly reflected into the eye, and, in order yet to discern in some measure large objects, he feels himself obliged always to seek shady, darkish situations, or to screen his eyes, out of doors, with a green shade or green glasses. This state is termed intolerance of light. (*Photophobia.*)

The amaurosis with morbid irritability of the retina and photophobia, is described by Beer as commencing with a peculiar sensation of fulness in the eyeball, joined with continually increasing, violent, and annoying luminous appearances, and a remarkable weakness of sight. These symptoms are soon followed by a stupifying, constantly increasing headache, during which the power of vision manifestly diminishes, without the slightest defect being perceptible, either in the eye itself or its surrounding parts. The patient, however, is always of an athletic constitution, or has symptoms of general or local plethora, or a phlogistic diathesis. This observation coincides with the view which I entertain of this part of the subject, namely, that the amaurosis beginning with irritability of the organ and photophobia, originates generally from an inflammatory affection of the retina.

In the amaurosis originating with symptoms of weakness and diminished irritability the sight is cloudy, and the patient finds that he can see better in a light than a dark situation. He feels as if some dirt, or dust, were upon his eyes, and is in the habit of frequently wiping them. His power of vision is greater after meals than at the time of fasting. His sight is always plainer, for a short time after the external use of tonic remedies, such as hartshorn, cold water, &c. Richter informs us of a person who was nearly blind, but constantly able to see very well, for the space of an hour after drinking champagne. He also mentions a woman entirely bereft of sight, who was in the habit of having it restored again, for half an hour, whenever she walked a quick pace up and down her garden.

When the disorder is accompanied with diminished sensibility in the eye in general, Beer coincides with Richter, respecting the temporary improvement of the sight after a nourishing meal, or drinking spirituous liquors; or when the patient's mind is elated with joy or anger, though such melioration of sight, it is true, is but of very short duration. (Also *Vetch on Dis. of the Eye*, p. 137.) On the other hand, it may be remarked, that every thing which tends to depress the passions and spirits, augments the imperfection of sight. Where marks of increased sensibility prevail, the above-mentioned circumstances exercise a transient disadvantageous operation; the patient carefully retires from every strong light, and frequently shelters his eye with his hand. (*Lehre von den Augenkr.* b. ii. p. 430.) Mr. Travers also knows patients, whose vision is benefited in a high degree, and others, in whom it is much deteriorated, by the quickened circulation of a full meal, and a few glasses of wine. The former, he says, are persons of spare and meagre habits; the latter plethoric. (*Synopsis of the Diseases of the Eye*, p. 157.)

According to Beer, this amaurosis, originating with diminished sensibility of the organ, usually comes on very slowly, and commences with the visus reticulatus, or nebulosus, without any alternation with a blinding glare of light; and the eyesight is sometimes considerably better, and sometimes weaker, which always depends upon the accidental operation of the above internal or external circumstances. The melioration of the eyesight never continues long, while the diminution of it not only remains, but gets worse and worse. It is not at all uncommon for this species of amaurosis to make its appearance as a night blindness, because common artificial light is much too feeble to make due impression upon the diminished sensibility of the optic nerve, and consequently these patients always show a partiality to a strong light. To such weak-sighted individuals, the flame of a candle, or the moon, appears as if covered by a dense veil, with an expanded halo round it of various colours. There is no complaint made of pain in the head or eyes; and no sensation of fulness or weight is experienced in the eyeball; much less are there any signs of the disease in the structure and form of the eye, or in the action of its irritable textures; but, when it has been long complete, it is usually conjoined with a debilitated habit.

In the simple uncomplicated species of amaurosis, all morbid appearances are absent, so that we are obliged to trust almost exclusively to the patient's assertion, that his sight is bad, or quite gone; and not unfrequently it is necessary, especially in judicial cases, to employ political artifices, in order to determine whether such assertion be true, particularly when the patient affirms that the blindness is restricted to one eye.

In this case we shall probably be assisted in our diagnosis by the slight degree of strabismus usually present, which arises from the patient being unable to fix the diseased eye steadily on any object. This degree of strabismus is noticed by Ackermann and Fischer as the surest sign of amaurosis. (See *Klinische Annalen von Jena*, st. i. p. 144.) And it is particularly pointed out by Richter as an invariable attendant upon amaurosis. The patient, says he, not only does not turn either eye towards any object, in such a manner that the object looked

at is in the axis of vision, but he does not turn both his eyes towards the same thing. This was regarded by Richter as the only symptom which we can trust, where implicit confidence should not be put in the mere assurance of the patient that he cannot see, while all the coats and humours of the eyes present their natural appearance. (See *Anfangsgr. der Wundarzn.* b. iii. kap. 14.) This observation is interesting to the military surgeon, amaurosis being a common affliction of soldiers, many of whom, however, endeavour to avoid service by pretending to labour under a disqualification which they well know does not necessarily produce any very considerable alteration on the natural appearance of the eye. There is another symptom of great value, when only one eye is quite blind, and the eyesight on the other side is perfectly undisturbed, namely, *if the sound eye be very carefully covered, the pupil of the blind one immediately expands, and the iris becomes quite motionless, notwithstanding the diseased eye be exposed to the strongest light possible.* However, this criterion is frequently wanting, because the amaurosis, unattended with any perceptible defect, except loss of vision, is seldom confined to one eye, but usually affects both. (See *Lehre von den Augenkr.* b. ii. p. 481-82.)

The gait and the cast of the eye in an amaurotic patient form another important characteristic of the disease. He advances towards us with an air of doubt and uncertainty in his movements, from which the cataractous patient is generally exempt, and instead of converging his eyes in the natural way towards an object, it is evident that there is something vacant and unmeaning in his look, the result of the eyes being directed parallelly, as if towards an object infinitely distant. In many cases there is oscillation, and in some the eyes stand completely fixed in the head. (*Mackenzie on Dis. of the Eye*, ed. 4, p. 1022.)

Imperfect movement in the lids also frequently accompanies amaurosis, and will usually indicate that the cause of the disease is such as to implicate the motor oculi and facial nerves also in the paralysis.

One of the most important incidental symptoms of amaurosis consists in the faulty size and shape and the imperfect movements of the pupil. When the amaurosis is complete, the most frequent state of the pupil is that of extreme dilatation, so that a mere ring of iris may be all that is visible, and its dimensions are not altered even when the strongest light is directed upon the retina. And in the incomplete cases, the movements of the iris are sluggish, and the pupil is larger than ordinary.

This is the state of numerous cases, but there are many exceptions. Sometimes, according to Richter, in the most complete and incurable cases, the pupil is of its proper size, and even capable of free motion (*Turbés, Recueil Périodique*, &c. t. ii. p. 319): and, occasionally, it is actually smaller and more contracted than natural. This aperture often continues extraordinarily large in the strongest light; but, in some instances, it is unusually small in every kind of light. (*Arrachard, Recueil Périod.* &c. t. i. p. 273; *Richter, Anfangsgr.* &c. b. iii. p. 424; *Beer, Lehre*, &c. b. ii. p. 435.) According to the latter writer, the pupillary edge of the iris rarely has its primitive shape, being generally more or less angular; either at some indeterminate point, or above and below, so as to resemble in some measure the pupil of the cat race; or towards

the nose, or temple, so as to have some similitude in its form to the pupil of ruminating animals.

Frequently, not only the size and shape of the pupil are faulty, but its position is unnatural, being inclined either upwards or downwards, or outwards or inwards, but most commonly in a diagonal line between inwards and upwards; and in these cases the pupillary margin of the iris never describes a regular circle, but is more or less angular. (*Beer*, vol. cit. p. 436.)

We have also the authority of Richter for asserting that, in particular instances, the iris not only possesses the power of motion, but is capable of moving with uncommon activity, so that, in a moderate light, it will contract, and nearly close the pupil. (*Anfangsgr. der Wundarzn.* b. iii. p. 424, ed. 1795.)

Two or three remarkable instances of the active state of the iris, in cases of amaurosis, were some years ago shown to me by Dr. Albert, then staff surgeon at the York Hospital, Chelsea, and I have since seen other similar cases. Most of the patients in question had not the least power of distinguishing the difference between total darkness and the vivid light of the sun, or a candle placed just before their eyes. Janin sometimes found the pupil capable of active motion in this disease, and Schmucker twice noticed the same fact. An example of complete amaurosis, with perfect motion of the irides, is recorded by Mr. Lawrence. It was attended by violent pains in the head, and proved incurable. (*On Diseases of the Eye*, ed. 3, p. 512.)

Such cases, Mr. Travers thinks, can only be explained by concluding the organ to be sound, and the cause of the amaurosis remote, or external to it. Thus, says he, in a case of circumscribed tumor, compressing the left optic nerve, immediately behind the ganglion opticum, although the blindness was complete, the iris was active. In two young ladies, in whom the eyes, as in the former case, were perfect, and the blindness complete, the iris was even vivacious; and there was the strongest presumptive evidence, from the symptoms, that the amaurosis was in the cerebral portion of the nerve. (*Synopsis*, p. 188.) Sometimes, when the retina of each eye is equally insensible to light, and the amaurosis of both eyes complete, the iris of each eye will be differently acted upon by the light, so that one pupil will be larger and its motions more lively than those of the other. Mr. Middlemore has seen several persons, who had amaurosis in a decided form in one eye, and only in a very slight degree in the other, in whom the mobility of the pupil, as tested in various ways, was much more considerable in the most diseased eye. The irritability of the iris, and the sensibility of the retina to light, do not, therefore, always correspond. (See *R. Middlemore on Dis. of the Eye*, vol. ii. p. 255.)

In some anomalous cases, when the strength of the light is suddenly increased, the pupil expands with more or less celerity.

It is observed by Mr. Travers, that if the retina be opaque, compressed, or unsupported, the iris mechanically disordered, or the ciliary nerves palsied, the pupil is inactive, independently of the state of vision. In the first of these cases, it is evident that the sight will be lost; but we continually see useful vision combined with the second and third, as after operations, in which the iris has been half destroyed, or has become preterna-

turally adherent, or in malformations, where it is half wanting; and in paralysis of the ciliary nerves, accompanying ptosis. (*Synopsis*, p. 188.)

Frequently, in amaurosis, when the sight of only one eye is lost, and the other retains its full power of vision, not the slightest defect can be discovered as long as the patient keeps both of them open; but, the instant the sound eye is completely covered, the iris becomes perfectly motionless, its pupillary margin assumes an angular shape, and the pupil expands, being sometimes evidently drawn towards the edge of the cornea. (*Beer, Lehre von den Augenkrank.* b. ii. p. 438.) This demonstrates the difference between the independent and the associated action of the iris.

Dr. Mackenzie thinks that the activity of the pupils, which sometimes exists in cases of total blindness, may be accounted for in the following manner. He says, "It appears to be absolutely necessary for the ordinary motions of that membrane (viz. the iris), not only that the iridal or ciliary nerves, and one or other or both retinae be sound, but that a certain degree of communication shall be kept up, between one or other or both retinae and the brain on the one hand, and between the brain and the iridal nerves on the other. It becomes, then, a question whether the brain may not be so affected with disease as to be incapable of acting as the organ of visual perception, and yet retain the power of communicating to the third nerve the impulse necessary for the usual motions of the pupil. If we suppose that the function of vision is accomplished only after the optic nerves reach the corpora quadrigemina, and thus communicate with the posterior part of the medulla oblongata, but that the association which undoubtedly exists between the optic nerves and the third pair is effected farther forward on the basis of the brain, we shall be able to afford at least a plausible explanation of the fact of the lively mobility of the pupils in certain cases of complete amaurosis. The third pair makes its appearance immediately behind the tuber cinereum, a part of the brain with which the optic nerves have a manifest connection. The third pair does not, indeed, appear to take its origin from the tuber cinereum, but from the central cineritious substance of the crura cerebri, bearing an analogy, along with the sixth and ninth pairs, the portio dura of the seventh, and the portion of the fifth pair which escapes the Gasserian ganglion, to the anterior roots of the spinal nerves; but it is surely not an improbable supposition, that the optic nerves, either where they cross the crura cerebri or more probably where they communicate with the tuber cinereum, form that link of connection with the third pair which they are universally acknowledged to do in some part or other of their course. A disease, then, affecting the corpora quadrigemina, or, in other words, the origin of the optic nerves, or affecting any part of the tractus opticus between the corpora quadrigemina and the communication between the optic nerves and the third pair, wherever that communication is effected, will, according to this view of the subject, produce blindness, but may leave unimpaired the influence of the optic nerves upon the third pair; while the cases of amaurosis in which the pupils are fixed and dilated, are probably owing either to more extensive disease, or to disease so situated as to affect that part of the

brain where the optic nerves communicate their influence to the third pair. Amaurosis with lively pupils has not unfrequently been found to depend on disease of the cerebellum."

He thinks the same theory "will also serve to account for the motions of the iris of an amaurotic eye, when the opposite sound eye is exposed to various gradations of light. Each optic nerve, dividing at the chiasma into two portions, one to the right and the other to the left side of the brain, is in communication with both nerves of the third pair, so that although the pupil of the diseased eye becomes expanded and fixed when the sound eye is kept shut, it instantly contracts when this eye is exposed to light, and so long as this is the case, performs exactly the same motions."

The pupil of an eye, affected with amaurosis, frequently does not exhibit the clear shining blackness which is seen in a healthy eye. When the disease is an effect of hydrocephalus, and occurs in a young subject, the pupil presents its natural black hue; but in elderly subjects, it is rarely the case that some degree of glaucoma does not accompany amaurosis. (*Mackenzie*, ed. 4, p. 1025.) In general, the pupil is of a dull glassy, hornlike blackness, which symptom alone is frequently enough to apprise a well-informed practitioner of the nature of the disease. It is, in the words of Mr. Travers, "little more than the healthy appearance of the humours in the eye of a horse." (*Synopsis*, p. 146.) Sometimes the colour of the pupil has an inclination to green; while, in other examples, this aperture seems to be dense, white, and cloudy, so that the complaint might easily be mistaken for the beginning of a cataract. This error, into which inexperienced surgeons are liable to fall, may generally be avoided by attention to the following circumstances. The misty appearance is not situated close behind the pupil, in the place of the crystalline lens, but more deeply in the eye. Nor is it in proportion to the impairment of sight, the patient being quite blind, while the misty appearance is so trivial, that, if it arose from the opacity of the crystalline lens, it could at most only occasion a slight weakness and obscurity of vision; at the same time, Richter acknowledges that it must be more difficult to avoid mistake when a beginning amaurosis is accompanied with this cloudiness of the eye, and, consequently, when the degree of blindness seems to bear some proportion to the degree of mistiness in the pupil. However, in this case, he maintains that the true nature of the disease may generally be known by comparing the ordinary symptoms of the two diseases. (*Anfangsgr.* b. iii. p. 14.) And, according to Beer, when the pupil is of a true dark gray, or greenish gray colour, a lateral inspection of the eye will show plainly enough that the cloudiness is in the vitreous humour or behind it. Sometimes the pupil appears reddish, quite red, or of a yellowish white colour (*Lehre von den Augenkr.* b. ii. p. 436); while, in other cases, the interior of the eye, a good way behind the pupil, seems white, and a concave light-coloured surface may be observed, upon which the ramifications of blood-vessels can be plainly seen. In particular instances, this white surface extends over the whole back part of the eye, while, in other cases, it only occupies a half or a small portion of it. This peculiar appearance has been ascribed to a loss of transparency in the retina itself, and a consequent

reflection of the rays of light. (*Haller, Element. Physiol.* t. v. p. 409.) Mr. Travers inclines to the opinion, that it arises from a deficient secretion of the choroid pigment, a preternatural adhesion betwixt the choroid coat and the retina, and a discoloration or resplendent appearance of the latter from this cause. (*Synopsis*, p. 148.)

A whiteness behind the pupil sometimes originates from the diseased mass, which, in fungus hæmatodes of the eye, grows from the deeper part of this organ, and gradually makes its way forward to the iris, attended with total loss of sight. Putting out of present consideration the change of colour within the eye, produced by fungus hæmatodes, the other palish changes behind the pupil are not confined, as Kieser supposes, to very old cases of amaurosis, because the alteration is described by Schmucker as taking place especially in examples the formation of which was quite sudden (*Vermischte Chir. Schrift.* b. ii.); and Langenbeck has recorded cases in which the same appearance happened in the early stage of the disease. (*Neue Bibl.* b. i. p. 64, &c.)

One criterion between amaurosis and incipient cataract, is the different appearance which the flame of a candle exhibits to the patient in the two affections. In incipient cataract, it appears as if it were involved in a generally diffused thin mist, or white cloud, which increases with the distance of the light; but in amaurosis, a halo or iris appears to encircle or emanate from the mist, the flame seeming to be split when at a distance. (*Stevenson on the Nature, &c. of Amaurosis.* Lond. 1821.)

The Ophthalmoscope, a contrivance for directing concentrated light into the interior of the eyes, is sometimes employed for exploring the condition of the deeper seated tissues. On this subject, Dr. Mackenzie observes:—"It may be possible by concentrating the sun's rays, or the strong light of a lamp or gas flame, with a double convex lens, and letting the focus fall within the eye, to discover in some cases pigmentary depositions in the vitreous humour, effusions of blood or exudations of lymph on the surface or in the substance of the retina, or between it and the choroid, varicosity of the retinal vessels, partial removal of the pigment in patches, separation of the retina from the choroid in consequence of subchoroid dropsy, &c. The same may be accomplished by means of a beam of strong light reflected from a mirror, as is done by the ophthalmoscopes of Helmholtz, Coccia, and others. Such examinations may confirm us in an unfavourable prognosis, already pronounced on other grounds, but are not likely to be either satisfactory or safe in the early and curable stages of the disease." (See OPHTHALMOSCOPE.)

If the pupil is *very much* dilated, if its mobility is *nearly* destroyed, if scintillations are present, and if the patient has recently been exposed to the operation of circumstances calculated to induce atonic amaurosis; then the decision that the case is of the latter kind is free from difficulty. (See *R. Middlemore on Dis. of the Eye*, vol. ii. p. 270.) This gentleman is satisfied, that the only circumstances, which can render it difficult to distinguish cataract from amaurosis, are, when mere atony of the retina, or atrophy of the optic nerve, *commences*, and especially, when either of these morbid states supervenes upon a cloudy state of the pupil; and, in

every such instance, where the slightest doubt exists, he recommends the eye not to be actively exerted.

For additional observations on the distinctions between incipient cataract and amaurosis, and glaucoma, see *Cataract* and *Glaucoma*.

Besides the above appearances of the pupil and iris, amaurosis is attended with other characteristic phenomena, which occur under certain circumstances, in the form, texture, and state of other parts of the eye, and adjoining organs. Thus, the patient oftens complains of a peculiar troublesome dryness of the eye, or of a sensation as if the eyeball were about to be pressed out of its socket; and, indeed, says Beer, one may sometimes hear a grating noise, and distinguish a fluctuation in the orbit behind the eyeball, when this organ is pressed upon by the finger, or moved in various directions, though neither its circumference be enlarged, nor any tendency to exophthalmia be really present. Nor is it very uncommon to find the affected eye preternaturally hard, soft, or even quite flaccid; but it is less common to find the dimensions of the globe of the eye increased, than the organ affected with atrophy. (*Beer*, vol. cit. p. 438.)

However, in organic amaurosis, a peculiar bluish gray tint of the sclerotic coat is frequently remarkable; and sometimes even a degree of bulging on one or more sides of the eye, or simply a loss of sphericity, its sides appearing flattened. A turgescence of the superficial vessels, especially of the long fasciculi of conjunctival veins, is likewise another symptom, frequently observed in organic amaurosis. (See *Travers's Synopsis*, p. 146.)

In this work are given the particulars of a dissection, in which a case of amaurosis was attended with a collapse of the retina from absorption of the vitreous humour.

Some of the principal morbid effects of amaurosis have been already described in speaking of the several defects of vision, which accompany an amaurotic weakness of sight. Besides these, however, there are others meriting attention. For instance, the patient feels in the eye and surrounding parts an irksome sensation, without any actual pain, and complains of a remarkable sense of fullness or weight in the organ. Amaurotic patients are also frequently attacked with sudden violent giddiness, usually ending in a considerable diminution of the eyesight, and sometimes in severe general headache. Occasionally they fancy that small atoms of dust are lodged under the eyelids, and are fearful of moving these parts, or the eye. It is also well known, that many persons become amaurotic while labouring under severe hemicrania, extending from, or to, the diseased eye; while, on other occasions, the most violent pains are confined, particularly to the region of the eyebrow, and have the appearance of being strictly periodical. In certain other cases, the pain is wandering, and shoots in every direction about the eyebrow. These painful feelings often precede the amaurotic blindness a considerable time, and often first take place when one or both eyes are already blind; but the pains and loss of sight are not unfrequently produced together. Lastly, some patients are met with, in whom the worst pains only last until the amaurosis is perfectly formed, when they gradually and permanently

cease. In all these painful cases of amaurosis, the pain and the blindness chiefly depend upon the same cause, and one is seldom the occasion of the other. Sometimes amaurotic patients experience such violent pain, that they lose their senses, and grow delirious; but, in these cases, if we can credit the assertion of Beer, important morbid changes in the bones of the skull, or the brain itself, are invariably noticed after death. (See *Lehre von den Augenkr.* b. ii. p. 439.) In some amaurotic patients, lethargic symptoms may be remarked; in others, restlessness; and, more rarely, delirium in all its degrees, either as a transient or permanent affection.

According to the observations of Mr. Travers, pain in the forehead and temples is a precursory symptom of amaurosis, diminishing in proportion as the dimness increases. When the amaurosis is perfect, it usually ceases altogether, *if the disease has its seat in the eyeball*. But when the pain is severe, remits imperfectly, and is quickly rendered worse by exercise, it is usually connected with organic disease of the brain. In this case, derangement and torpor of the primæ viæ, loss of strength and flesh, disposition to stupor, occasional confusion of intellect, inaptitude to exertion, and paralysis of one or more muscles, will be concomitant symptoms. (*Synopsis*, &c. p. 167.)

Dr. Mackenzie observes that amaurosis without pain generally depends on atrophy of the optic nerves. If it be attended with pain either constant or intermittent, there is probably some organic affection of the brain, or cause of pressure within the cranium. From a careful investigation of the seat, extent, and nature of the pain, we may often arrive at a probable conclusion respecting the state of the cerebral circulation, or we may obtain evidence of the existence of some deposition or formation within the head causing pressure. (Ed. 4, p. 1028.)

Paralytic appearances may precede amaurosis, either in the vicinity of the eye, or in the muscles of the face, or in a distant situation, as the extremities. Sometimes they accompany the disease, and sometimes closely follow the weakness of sight, being not unfrequently the forerunners of a fatal attack of apoplexy.

In the same way, convulsive symptoms may be conjoined with amaurosis; and when they first occur in the complete stage of the latter disease, Beer pronounces them a very unfavourable omen for the patient's life.

Likewise, when in a case of perfect amaurosis, several of the other senses are affected; when the hearing and then the smell and taste are lost, and afterwards the memory and other intellectual powers fail, the patient's speedy dissolution may be expected. (See *Lehre von den Augenkrankh.* b. ii. p. 441, Wien. 1817.)

CAUSES OF AMAUROSIS.

In some cases, the cause is of a *local, direct*, and *mechanical* nature; such as the pressure of a tumour on the optic nerve. In others, it is of a *local*, but *vital* kind; such as a plethoric, or congested state of the blood-vessels of the brain or eye. In a third set of cases, the cause is *general* or *constitutional*; such as exhaustion, consequent to profuse or continued loss of some of the fluids of the body. (See *Mackenzie on Dis. of the Eye*, p. 901, ed. 2.)

The directions of Mr. Middlemore for tracing the cause of amaurosis deserve notice. The surgeon should first investigate the condition of the eye and the eyelids; he should observe whether the upper lid drooped, whether there was any degree of strabismus, and whether the sympathetic and associated movements of the eyes were unaltered; he should then notice the state of the cornea, its clearness and its form; the state of the pupil, its size, its figure, its degree of motion, and also the distance of the iris from the cornea, as well as its colour and the general appearance of its texture, and whether it be convex or concave, or preserve its natural place; the state of the humours in reference to their transparency, and particularly notice whether any deep-seated buffy or dusky cloudiness were present, and whether the eyeball were increased in vascularity, or changed in colour, figure, size, or consistence. Mr. Middlemore further recommends the effect of belladonna on the pupil to be noticed; and the eye to be examined under its influence, if any influence at all be produced by it, and in various degrees of light, and in connection with the pupil of the opposite eye. The state of the pupil is to be observed at the moment when the lids of both eyes are suddenly separated, and also when the lids of the sound eye are closed, and those of the diseased one separated. Each pupil is also to be examined separately, so as to ascertain its extent and facility of motion.

Mr. Middlemore advises inquiry to be made into the patient's habits, temperament, disposition, and state of mind; whether any visceral disease be present, and what its nature; whether there be any temporary disorder in the alimentary canal; whether the patient is suffering or has been recently suffering from gout, rheumatism, scrofula, or syphilis; whether he has passed through any severe mercurial treatment; whether he has suffered from apoplexy, epilepsy, paralysis, severe fever, inflammation, or concussion, or other injury of the brain; how long the disease has existed; what remedies have been tried, and what their effect. (See *R. Middlemore on Dis. of the Eye*, vol. ii. p. 255.)

Age cannot be considered a predisposing cause of amaurosis in the same degree that it is of cataract; for there are many more blind persons who have been deprived of their sight by amaurosis in their best days, than old persons thus attacked. Amaurosis spares no age—not even the new-born infant. Mr. Lawrence concurs in this statement, adding his belief, however, that amaurosis is most frequent at or after the middle period of life, especially about the cessation of menstruation in females, and the corresponding age in the male. (*On Diseases of the Eye*, p. 517.)

The following statement, in relation to this part of the subject, appears correct:—"There are certain ages at which, from particular circumstances, amaurosis is most commonly witnessed, and for the most part merely as a functional, or sympathetic affection. In the first place, it may be congenital, with or without being evinced by any defect in the form or the magnitude of the eye, or any of its parts, although the globe generally acquires under such circumstances a rolling or unsteady motion. Amaurosis may be produced by hydrocephalus, which disease occurs most frequently in children; by convulsions; and by the

irritation connected with dentition, or by the presence of worms in the stomach or intestines. These are the circumstances associated with very early life, with which amaurosis is most commonly connected. At the period of puberty, it is sometimes induced by vitiated habits, and by certain conditions of, and changes in, the genital system. Again, the period of pregnancy and suckling are favourable to its origin; the former, by the pressure of the gravid uterus on the large venous trunks; and the latter, by enfeebling the system generally, and very probably also by over exciting and deranging that sympathy which exists between the uterus, the mammæ, and the retina, and with the precise nature of which we are not fully acquainted. The final cessation of menstruation is the next season at which amaurosis is most likely to take place; and, lastly, extreme age is a strong predisposing cause of amaurosis." (See *Middlemore on Dis. of the Eye*, p. 252.)

Four forms of *congenital* organic amaurosis are noticed by Mr. Travers. One, in which the eye is preternaturally small, soft, and even flaccid; the iris tremulous, and not influenced by belladonna; and the globe affected with tremour, and not subject to the control of the will. A second, depending on a deficiency of the pigmentum nigrum; the organ is tremulous, strong light produces uneasiness, and vision is dazzled and confused. The vessels of the choroid give the interior of the eye a deep red tinge. A third case is that in which the sclerotica so encroaches upon the cornea, that the latter is scarcely wider than the pupil. In the fourth kind of congenital amaurosis, described by Mr. Travers, the eyes move in concert, as if attracted by a faint perception of light; but the infant is blind: no marks of organic derangement can be seen; but the disease may be connected with a morbid state of the thalami, or optic nerve. (*Synopsis*, p. 153, 154.)

Neither do sex and race affect the frequency of the complaint; but dark eyes are sometimes alleged to be more disposed to amaurotic blindness than such as are light-coloured. According to Beer's experience, for every gray or blue eye affected with amaurosis, there are five and twenty or thirty brown or black ones thus diseased. L. Winslow, Weller, and Sanson likewise regard dark eyes as most subject to amaurosis. In this country, I believe, it is found that the mere colour of the eye has not the influence here represented in predisposing to amaurosis. (See *R. Middlemore on Diseases of the Eye*, vol. ii. p. 252.)

More frequently than cataract, amaurosis is found to be a true hereditary disease;—this is so much the case, that most of the members of a family, for more than one generation, may lose their sight from amaurosis at a certain period of life. Beer was acquainted with more than one family in which this happened; and, what merits attention, the women of one of these families, down to the third generation, became completely and permanently blind from amaurosis on the cessation of the menses, while all the others, who had had children, were unaffected. But the males of this unfortunate family, who, as well as the females, have very dark brown eyes, all seem to be weak-sighted, though none of them are yet blind. (*Lehre von den Augenkrankheiten*, b. ii. p. 443.)

In women, especially those with black eyes, the time when the menses stop is considered by Beer

a likely period for the commencement of amaurosis.

One of the less common causes of amaurosis is an idiosyncrasy in relation to this or that sort of nutriment or medicine, or this or that particular state of the body. Here is to be reckoned the amaurotic weakness of sight, or the perfect amaurosis, which comes on at the very commencement of pregnancy, and subsides after delivery, but always attended with dyspepsia and insuperable vomiting. This species of amaurosis, however, should be carefully distinguished from that which sometimes first originates in the final months of pregnancy, and chiefly from strong and long-continued determination of blood to the head and eyes, particularly when the bowels are at the same time loaded, and the patient constipated. This latter case usually continues till after delivery; or, if the labour be tedious, difficult, and attended with considerable efforts, the blindness may first attain its complete form at the time of delivery, and not afterwards subside.

Beer saw a young Jewess, who, at the very beginning of her first three pregnancies, which followed each other quickly, regularly lost her sight, becoming completely amaurotic between the third and fourth months, and, on the two first occasions, she continued blind till after delivery; but, in the third instance, the power of vision never returned at all. (See also *Démours, Traité des Mal. des Yeux*, t. i. p. 380.) Beer twice had under his care another woman, who was attacked with amaurosis whenever she drank chocolate; but, upon leaving off that drink, she never afterwards had any complaint in her eyes.

According to Richter, the causes of amaurosis may be properly divided into three principal classes, the differences of which indicate three general methods of treatment.

The first class of causes depends upon an extraordinary plethora and turgidity of the blood-vessels of the brain, or of those of the optic nerves and retinae, upon which last parts a degree of pressure is thereby supposed to be occasioned. A considerable plethora, especially when the patient heats himself or keeps his head in a depending position, will frequently excite the appearance of black specks before the eyes, and sometimes complete blindness. A plethoric person (says Richter), who held his breath, and looked at a white wall, was conscious of discerning a kind of network, which alternately appeared and disappeared with the diastole and systole of the arteries.

Richter thinks it likely, that the disease is thus produced, when it proceeds from the suppression of some habitual discharge of blood, from the neglect to be bled according to custom, the stoppage of the menses, and the cessation of hemorrhage from piles. In the same manner, the complaint may be brought on by great bodily exertions, which determine a more rapid current of blood to the head. Richter informs us of a man who became blind all on a sudden, while carrying a heavy burden up stairs. He tells us of another man, who laboured excessively hard for three days in succession, and became blind at the end of the third day. Pregnant women, in like manner are sometimes bereft of their sight during the time of labour. Schmucker has recorded a remarkable instance of this in a strong young woman thirty years old, and of a full habit. Whenever

she was pregnant, she was troubled with violent sickness, till the time of delivery, so that nothing would stop in her stomach. She was bled, three or four times without effect. Towards the ninth month her sight grew weak, and for eight or ten days before parturition, she was quite blind. The pupil of the eye was greatly enlarged, but retained its shining black appearance. She recovered her sight immediately after delivery, and did not suffer any particular complaints. Schmucker assures us, that he has been three times a witness of this extraordinary circumstance. (*Vermischte Chir. Schriften*, band ii. p. 6, ed. 1786.) Richter speaks of a person, who lost his sight during a violent fit of vomiting. Schmucker acquaints us, that it is not uncommon for soldiers, who are performing forced marches in hot weather, to become suddenly blind.

Beer also coincides with Schmucker, Richter, and others, in regarding, as a frequent cause of amaurosis, repeated and long-continued determinations of blood to the head and eyes, produced by various circumstances, viz. by pregnancy; a tedious and difficult labour; lifting and carrying heavy burdens, especially with the arms raised up; all kinds of work in which the eyesight and intellectual faculties are intensely exerted, with the head bent forwards, and the abdomen compressed, as is the case with shoemakers, tailors, &c.; every sudden stoppage of natural, or preternatural long-established discharges of blood, as that of the menses lochia, or hemorrhoids; the omission of habitual venesection at some particular season of the year; severe and obstinate vomiting; forced marches in hot, dry weather; scrofulous and other swellings of considerable size in the neck, pressing upon the jugular veins, and obstructing the return of blood from the head; the use of a pediluvium, or warm bath, the water of which is of high temperature; hard drinking; violent gusts of passion; frequent and obstinate constipation; and hard straining at stool. These causes are more likely to occasion amaurosis, in proportion as the individual is young and plethoric. The causes of that amaurosis which is characterised in its first stage by increased sensibility of the eye, and intolerance of light, are referred by Professor Beer to circumstances which produce a long and repeated determination of blood to the head and eyes. (*Lehre von den Augenkr.* b. ii. p. 446 and 483, &c.)

Mr. Lawrence regards amaurosis, in its most frequent and important form, that which is seated in the eye itself, as generally the result of inflammation of the nervous structure; including under that phrase all degrees of increased vascular action, whether designated as fulness, turgescence, determination, congestion, or as inflammation in its more limited sense; and the usual consequence of inflammatory disturbance, that is, organic change, permanently destroying the function of the part. When, says he, we advert to the structure of the retina, we must suppose that it would be liable to such affections; we find it composed of minute ramifications of the arteria centralis retinae, and on this network of vessels the nervous pulp is expanded. The state of the retinae, when examined after death, in amaurotic eyes, accords with these views; it exhibits those changes which long-continued inflammatory disturbance would produce; it has been found thickened, opaque, spotted, buff-coloured, tough, and, in some cases, even ossified.

The preceding doctrine is, however, judiciously qualified by its restriction to the disease as seated in the eye itself. The retina and optic nerve, Mr. Lawrence admits, with other surgeons, may be disordered sympathetically, as the stomach may be disordered, without any change visible on dissection.

The second class of causes are supposed to operate, by weakening either the whole body, or the eye alone, and they indicate the general or topical use of tonic remedies. In the first case, the blindness appears as a symptom of considerable universal debility of the whole system; in the second case, it is altogether local. Every great general weakness of body, let it proceed from any cause whatsoever, may be followed by a loss of sight. Amaurosis is sometimes the consequence of a tedious diarrhoea, an attack of cholera, profuse hemorrhage, and immoderate salivations. (See *Travers's Synopsis*, p. 144.) Richter informs us of a dropsical woman who became blind on the water being let out of her abdomen. According to the same author, no general weakening causes operate upon the eyes, and occasion total blindness, so powerfully and often as premature and excessive indulgence in venereal pleasures. Mr. Lawrence does not coincide in some of the foregoing views. "Those," says he, "who have considered amaurosis to arise from debilitating causes, have considered that debility and atony of the nerve may be produced by all those circumstances which debilitate the system generally, such as loss of blood from profuse hemorrhage, diarrhoea, copious salivation, &c. I have never seen amaurosis produced by such causes. That great anxiety and grief may favour the occurrence of amaurosis, I am inclined to allow; for it is not improbable that severe impressions of that kind may produce inflammatory excitement in the brain or eyes; but I think we cannot, without more direct proofs, admit the influence of debilitating causes generally in the production of amaurosis. The most clear instance of any directly debilitating cause producing amaurosis, is that of protracted suckling."

The causes, which operate locally in weakening the eyes, are various. Nothing has a greater tendency to debilitate these organs than keeping them long and attentively fixed upon minute objects. But, however long and assiduously objects are viewed, if they are diversified, the eye suffers much less than when they are all of the same kind. A frequent change in the objects which are looked at, has a material effect in strengthening and refreshing the eye. The sight is particularly injured by looking at objects with only one eye at a time, as is done with telescopes and magnifying glasses; for, when one eye remains shut, the pupil of that which is open always becomes dilated beyond its natural diameter, and lets an extraordinary quantity of light into the organ. The eye is generally very much hurt by being employed in the close inspection of brilliant, light-coloured, shining objects. Amongst the occupations enumerated by Mr. Travers as particularly exposing persons to amaurosis, are those of needleworkers, writers, draughtsmen, inspectors of linen and scarlet cloths, and of new bank notes; money counters, smiths, stokers in iron-furnaces and glass-houses, tavern-cooks, watchmakers, engravers, philosophical instrument makers, sea officers, &c. (*Synopsis*, p. 144.) They are greatly mistaken, says Richter, who think that they save their eyes, when they

illuminate the object which they wish to see in the evening with more lights, or with a lamp that intercepts and collects all the rays of light, and reflects them upon the body which is to be looked at. Richter mentions a man, who, in the middle of winter, went a journey on horseback, through a snowy country, while the sun was shining quite bright, and who was attacked with amaurosis. He speaks of another person, who lost his sight in consequence of the chamber in which he lay being suddenly illuminated by a vivid flash of lightning. A man was one night seized with blindness as his eyes were fixed on the moon. Richter also expresses his belief, that a concussion of the head, from external violence, may sometimes operate directly on the nerves, so as to weaken and render them completely paralytic.

Beer corroborates the foregoing statement; for, he says, amongst the most frequent causes is to be considered every abuse of the eyesight, especially in dark-eyed persons, as a long and close inspection of one object, particularly with a microscope, when the thing examined is very brilliant, or reflects back much light into the eye. Hence, the view of jewels at night, and long journeys through snowy countries, are conducive to the disease. In this respect, every kind of employment which strains the eyes much, and requires a strong reflected light, must be considered injurious. (See also *Travers's Synopsis*, p. 144.) Thus reverberating lamps, like Argand's; the view of a white wall illuminated with the sun's rays; and looking a long while at the moon, or more especially the sun, with the unassisted eye, are circumstances likely to bring on the disease. That a flash of lightning, especially when it suddenly wakes a person in the night-time out of a sound sleep, may produce an amaurotic amblyopia, in an irritable eye, or even perfect blindness, is a well known fact: and it is on the same principle, that going suddenly out of a dark bed-room, immediately after waking in the morning, into an apartment that commands an open extensive prospect, must be hurtful to an irritable eye, though the bad effects may only come on slowly. Here is also to be included every kind of over irritation of the eye by light, as happens to typhoid patients, when they lie with their eyes open all the day in a large sunny chamber.

In the weakness of vision (*asthenopia*) brought on by over exercise of the sight, there is some difference of opinion as to the precise nature of the changes in the optic apparatus. Dr. Mackenzie considers that the disorder depends in a great measure on a loss of power in the apparatus for the focal adjustment of the eye, and that the effort necessary for adjustment cannot be sustained; the focal length of the eye can no longer be shortened as it should be, the letters of a book necessarily fade from before the sight, and a feeling of fatigue creeps over the eye. It is probable that the cause of impotency resides not in the ciliary circle, nor in the ciliary nerves merely, but in the third nerve and other muscular nerves of the eye generally. The contraction of the recti and obliqui, then, so necessary for keeping the eye in a state of libration for directing it along the lines of a printed page, for converging the two eyes to the same point, and perhaps for compressing the globe of the eye so as to maintain an increased distance between the retina and the cornea, must in this

case gradually give way under the effort demanded, so that these muscles fall into a state of minimum contraction. The consequence is, that at length the upper eyelid drops, and the patient is obliged to indulge in that cessation of visual exertion which experience has taught him will regenerate his exhausted powers of sight, and enable him by and bye to resume his labours. With reference to this statement of Dr. Mackenzie's, Mr. White Cooper thinks that "it is highly probable that in the earlier stages of this affection, and in the slighter cases, an enfeebled condition of the adjusting organs is the main fault; but has no doubt that congestion is speedily superadded, and that this local congestion is, in the majority of cases, in connection with general debility. In many cases the vessels of the eye have lost their tonicity; a trifling effort at reading visibly reddens the surface of the globe, and with a lens many small vessels may be seen distended with blood; from this, in connection with the symptoms, we may predicate the state of the deeper tissues. It is probable that the great advantage derived from cold applied to the eye itself, from iron, and from general invigorating measures, is referable to the effect produced by such remedies in restoring tone to the weakened vessels and imparting vigour to the nervous apparatus. When, however, the congestion has proceeded beyond a certain point, other treatment becomes necessary."

Mr. Dalrymple also is of opinion that the symptoms are produced by congestion, and the following quotation explains his view of the effect produced by over distention of the blood-vessels in the delicate structures of the eye:—

"When we recollect that in health the sclerotic and cornea are tough, inelastic, and resisting tissues, and that the fluids within the eye are so nicely balanced that no vacuity is left, and that no undue pressure is perceived,—when we remember also that the retina is interposed between the choroid and the incompressible vitreous body,—we shall readily perceive how increased bulk from congestion of the vascular tissue must exert a direct and injurious pressure upon the most delicate of nervous structures; how, in fact, this important organ becomes as it were benumbed by compression, and its functions and sensibilities to the pictured image presented by the rays of light interfered with, altered, or suppressed. While this effect is being produced on the special properties of the retina, we see also that the ciliary nerves that traverse the exterior of the choroid become in like manner compressed against the sclerotic, and as these are in part the channels of the common sensation of the globe, pain is induced; first of a sense of distention; secondly, of dull aching; and, lastly, pain in the brow or forehead, partaking somewhat of a neuralgic character induced by radiation to the frontal branches of the first division of the fifth pair.

The cause of amaurosis is often suspected to depend upon local or constitutional debility, proceeding from impairment of the nerves in general, or of the nerves of the head, especially those of the forehead and eyebrow; either in consequence of falls from a considerable height, or of concussion with the weight of the whole body upon the heels; blows on the head; concussions or contusions of the eyeball. Some of the cases of amaurosis from blows on the temple or the eye, observed by Mr.

Travers, were attended with signs of disorganisation; some were superficially inflamed; and others presented no external appearance of injury. It is not always the eye on the struck side of the head that is affected. (*Synopsis*, &c. p. 152.) If we are to believe Beer, considerable direct weakness, leading to amaurosis, may arise from cholera, long-continued diarrhoea, salivation, and the incessant spitting of tobacco smokers; bleedings; injudicious tapping of the abdomen; excessive indulgence in venery, and the misemployment of issues. A general debility, which has the worst effect on the eyes, may also arise from long trouble, especially when the diet is poor and bad; also from a deficiency of proper food, long watching, or violent and sudden fright. The amaurosis following typhus, without any unusual irritation of the eye by light, Beer refers to general debility. (*Lehre von den Augenkr.* b. ii. p. 449.)

Like nervous deafness, amaurosis sometimes follows typhus and scarlet fever, and the various forms of acute constitutional disease. Mr. Travers has several times met with it as a consequence of infantile fevers. He observes, that it is also sometimes a consequence of chronic wasting diseases, in which organic changes interrupt the nutrition of the system. He has seen a rapid and severe salivation, instituted for a remote affection, and where no disease had previously affected the eyes, terminate in gutta serena of both. (*Synopsis*, p. 155.)

The susceptibility of the retina is conceived by Mr. Middlemore to be capable of being at once directly depressed, without going through the process of inflammation, in the same way as the nervous power of other parts of the system may be lowered or taken away by powerfully depressing and rapidly enervating agents. (*On Dis. of the Eye*, vol. ii. p. 247.)

With regard to the doctrine, that certain forms of amaurosis are diseases of debility, Mr. Lawrence expresses his disbelief in its correctness, and asserts that the only successful treatment of amaurotic affections is found, with few exceptions, to be variously modified antiphlogistic. (*On Diseases of the Eye*, ed. 3, p. 524.) Whether the amaurosis resulting from typhoid fevers, of which I have seen several instances, proceed from debility, or from too great a determination of blood to the head, may admit of dispute; but I conceive that, in many of such cases, tonic treatment is clearly indicated, if not for the eye itself, certainly for the generally enfeebled state of the health, with which the amaurosis is connected. Yet the doctrine, that fulness and congestion of the vessels originally lead to the amaurotic affection, may be more correct than the theory which refers the blindness simply to weakness. However, as the amaurosis generally does not show itself till an advanced stage of fever, or that of great debility, and as it only recedes as the patient regains strength, it can hardly be considered as a case in which any other treatment than tonic can be availing.

The third class of causes consists of irritations, most of which are asserted to lie in the abdominal viscera, whence they sympathetically operate upon the eyes. The observations of Richter, Scarpa, and Schmucker, all tend to support this doctrine. Many amaurotic patients are found to have suffered much trouble, and long grief, or been agitated by repeated vexations, anger, and other passions, which have great effect in disordering the bilious

secretion, and the digestive functions in general. Richter tells us of a man, who lost his sight, a few hours after being in a violent passion, and recovered it again the next day, upon taking an emetic, by which a considerable quantity of bile was evacuated. A woman is also cited, who became blind whenever she was troubled with acidities of the stomach. (See *Anfangs. der Wundarzn.* b. iii. kap. 14.) However, according to Beer, if the case from worms be excepted, imperfect amaurosis seldom depends upon disorder of the gastric organs. (*Lehre von den Augenkr.* b. ii. p. 456.); a very important difference from the statements of Schmucker, Richter, and Scarpa. The close sympathy between the stomach and the eyes is well illustrated by a case referred to by Mr. Lawrence, where an amaurosis, with fixed pain over the eyebrow in a child, was not relieved by purging and other depletive measures; an emetic was at last given; and, under its action, a bead was rejected from the stomach, and the amaurosis immediately disappeared.

Just as amaurosis is frequently a pure symptomatic effect of various disordered states of the constitution, so may different morbid changes, occasioned in the eye by those states of the health, become the proximate cause of amaurosis, as cirsophthalmia, fungus hæmatodes, dissolution of the vitreous humour, glaucoma, &c.

One case, very analogous to amblyopia senilis, is believed to depend upon a diminution of the pigmentum nigrum, which secretion, in some individuals earlier and more considerably, in others later and in a slighter degree, recedes with other secretions of a different nature. (See *Beer's Lehre von den Augenkr.* b. ii. p. 451, &c.) Mr. Middlemore is certain that he has met with cases in which a diminution in the quantity of the choroid pigment was the sole defect in the eye, and constituted the adequate and efficient cause of impaired vision. Cases of this description, he says, are for the most part attended by a contracted pupil and great intolerance of light; and vision, though seriously impaired, is seldom destroyed. (*Op. et vol. cit.* p. 273.)

I think with Mr. Travers, that the history and concomitant appearances of amaurosis will often denote whether the case is *organic* or *functional*. "For example, diseased changes in the situation or texture of the eyeball, or in the brain, a hemiplegia, or partial paralysis, with other signs of apoplectic or hydrocephalic pressure, whether resulting from an injury of the head, or otherwise, or an acute deep-seated inflammation, whether accompanied by a visible opacity or not, point out the organic nature of the affection. I have seen (continues Mr. Travers) such an amaurosis produced by abscess in the cerebral substance, and by medullary disease of the cerebrum. On the other hand, I have known the following distinct sources of irritation produce functional amaurosis, viz. a wound of the scalp, caries of the skull, abscess and caries of the antrum maxillare, with excessive oedema of the integuments of the lids and cheek, a large abscess under the masseter and muscles of the cheek, and an abscess at the extremity of a molar tooth, while the crown of the tooth was sound. In all these cases, it is to be understood that the eye was sound, and the orbit was untouched by the disease of the parts in the vicinity, to which the amaurosis was clearly attributable. In like manner, an excessive use, or

rather abuse, of the visual faculty, the disordered functions of the stomach, liver, uterus, &c., sudden and alarming depletion, excessive or obstinately suppressed secretions, difficult dentition, the presence of worms in the intestinal canal, and the deleterious effects of noxious agents upon the organ, or the system, are sufficiently obvious causes of the functional amaurosis." (*Synopsis, &c.* p. 142.) In general, recent cases afford a greater prospect of cure than others of long standing; and the same may be said with respect to examples, in which the eyesight is merely lessened and not completely extinguished.

Amaurosis is occasionally caused by, or associated with, hysteria, hypochondriasis, epilepsy, or convulsions, but in these cases is rarely permanent, and usually subsides as soon as the spasmodic, epileptic, or convulsive attack is over. However, the complaint may begin at two periods, viz. either during such an attack, or (what is more uncommon) afterwards, and it never loses its symptomatic character. The pupil, which is much dilated, always remains perfectly clear and of a shining blackness, even when the disease has induced entire blindness; but a slight dull pain in the forehead, especially about the eyebrow, constantly preceding and accompanying the blindness, generally lasts a good while after the amaurosis has completely subsided.

As this amaurosis is merely a symptomatic effect of the above general disorders, its removal must entirely depend upon the success with which their treatment is conducted. (*Beer, Lehre von den Augenkr.* b. ii. p. 506—510.)

With respect to *rheumatic amaurosis*, we do not in this country recognise any distinct form of amaurosis entitled to the name of rheumatic, though Beer has minutely described such a case. No doubt a certain proportion of amaurotic patients suffer from rheumatism; but I agree with those pathologists who do not acknowledge rheumatism as having been clearly proved to be a cause of amaurosis.

Gouty Amaurosis.—According to Mr. Travers, gout attacks the eye through the medium of the stomach. Vomiting occurs, with pain in that organ, on the subsidence of an inflammation in the extremities, and is succeeded by violent pain in the head. The loss of sight, he adds, is sudden and permanent. (*Synopsis, &c.* p. 163.) The gouty amaurosis, described by Beer, is perhaps badly named: at all events, there are some circumstances in its history which must create doubts about its dependence upon gout. "We can admit," says Mr. Lawrence, "that the nervous structure of the eye may be diseased in the rheumatic and gouty, as well as in other persons; but it will require clearer evidence than we possess at present to show, that there are distinct gouty and rheumatic amauroses." (*Lawrence, op. cit.* p. 510.) When we find Beer describing one form of gouty amaurosis as taking place only in dark-eyed slender maiden ladies, who have suffered from scrofula in their childhood, or from other severe diseases at a later period, and whose menses are irregular, or have ceased, we must regard his evidences of gouty amaurosis as vague and fanciful.

When *amaurosis proceeds from disease of the optic nerves, or their sheaths*, it comes on slowly, and rarely attacks both eyes together. It commences with a black cloud, which grows more and more dense, and with a troublesome, alarming,

perversion and disfigurement of every object, without the least painful sensation in the eye or head. The patient merely complains of a slight sensation of dull pressure at the bottom of the orbit, as if the eyeball were about to be forced from its socket, of which displacement, however, there is not yet the smallest appearance. In the very beginning of the disease, the pupil is already considerably dilated, and the pupillary edge of the motionless iris presents angles at several points, the pupil sometimes representing an irregular pentagon, or hexagon. By degrees, though very slowly, a glaucomatous change of the vitreous humour ensues, and afterwards of the lens itself; the only species of glaucoma which Beer has ever noticed quite unattended with a varicose affection of the blood-vessels of the eye. At last the globe of the eye becomes perceptibly smaller than natural; but a complete atrophy does not ensue.

The morbid changes which Beer had himself ascertained by dissection, consist in a real induration of the optic nerves, and an adhesion of them to their sheaths, while within the skull these ash-coloured, gray, very much diminished nerves, presented no vestige of medullary structure even as far as their origin from the brain. On the contrary, the optic thalamus presented externally its natural appearance. The retina seemed to have lost its pulpy matter, was tough, not easily torn, and appeared to consist but of a vascular membrane. In one example, although both eyes had been completely deprived of sight together, Beer found only the retina and optic nerve of the left side in this state of atrophy as far forwards as the point of union on the sella turcica. On the other hand, the optic nerve of the right eye was hard, without being in the least dwindled, and was closely adherent to its external coverings. Anteriorly to their decussation, nothing at all preternatural in either nerve could be discerned. But the left corpus striatum was so indurated, that a very sharp, strong scalpel was required for its division, though in colour and shape it was perfectly natural. On this side, also, the plexus choroides was entirely wanting. In three amaurotic patients of this kind, Beer found hydatids between the coverings of the optic nerve; and where such hydatids lay, the medullary matter seemed to have been displaced by their pressure. With the utmost care, he could not trace the ophthalmic ganglion.

Raw also found on the optic nerve a large hydatid, which had produced amaurosis. (*Obs. Anat. Rarior. Obs. 2.*) In Mr. Heaviside's museum there was a preparation of the optic nerve of an amaurotic eye, where a tumor of considerable bulk had grown from the neurilemma. (See *Wardrop's Essays on the Morbid Anatomy of the Human Eye*, vol. ii. p. 157.) In this work are specified examples of various other morbid changes of the optic nerve, especially calculous concretions within it, the presence of a viscid, muddy, gray, fluid, in the thickened neurilemma, instead of pulp, atrophy of the nerve, &c.

An instance is recorded by Haller (*Opusc. Pathol. Obs. 65*, p. 172.) in which a calcareous mass was found betwixt the membrane of Ruysch and the vitreous humour. According to Beer, there is preserved in the pathological and anatomical museum of the general hospital at Vienna, an eye distended with a similar osseous mass, without the capsule of the lens being at all affected.

Magendie states, that he has seen the retina transformed into a fibrous membrane; though Andral suspects that the change could not have happened in the nervous expansion itself, but rather in the very fine cellular substance between it and the choroid coat. (*Anat. Pathol. t. i. p. 272.*) An osseous capsule also, sometimes produced within the eye, and usually regarded as an ossification of the retina, he offers good reasons for setting down as really an ossification of the cellular tissue between the retina and choroid tunic. (*Op. et vol. cit. p. 297.*)

Various other swellings in the orbit, as, for instance, encysted tumours, &c., may and must gradually produce complete amaurosis by their pressure upon the optic nerves and retina. Some of these cases are usually characterised by a protrusion of the eye from its socket. (See *EXOPHTHALMIA*.) Cases depending upon atrophy of the optic nerves are recorded by Dr. Monteith. (See *Weller's Manual*.) Mr. Langstaff has some interesting specimens of enlargement in front of the third ventricle, the parietes of which bulge so as to press upon the optic nerves, and thus to account for the amaurosis under which the patients laboured.

In another instance, the macula lutea, which is naturally a yellow spot near the centre of the retina, was found black. (*Mém. de la Société Méd. d'Emulation*, an. 1798.)

When amaurosis proceeds from disease of the skull or brain, it usually attacks both eyes together, or at least one soon after the other, the blindness also commencing very slowly, with appearances as if every object looked at were perverted or disfigured. However, there is no black cloud, but rather an obscurity or confusion of every object. The disease in this stage is also accompanied with frequent giddiness, ugly luminous spectra, and, for the most part, with aversion to light, uncommonly lively motions of the iris, a contracted pupil, angles in the upper and lower portions of the pupillary margin of the iris; an evident turgescence of the blood-vessels of the eye, gradually augmenting with most violent headache into actual cirsophthalmia; frequent convulsive motions of the eyes and eyelids, and strabismus of one or both eyes, ending in a true deviation of one or both these organs from their natural positions. Under these symptoms, vision is afterwards entirely abolished; and the headache, though subject to remissions, grows so much worse, extending back to the spine, that the patient is often nearly frantic, and, indeed, after a time, a destruction of the external senses happens, followed by that of the intellectual faculties. The first of the external senses which is lost is always the hearing, which infirmity is next followed by loss of the smell or taste, or both these senses together; and then the memory and other intellectual powers decline. In this stage of the disorder, the eyeball not unfrequently protrudes from the orbit; a pathognomonic symptom, to which Beer attaches great importance, because it is an infallible criterion of a diseased state of the bones of the orbit, of the parts which invest this cavity, and of the optic nerve and dura mater, in the sella turcica. In such cases, complete mania now usually follows, and this sometimes in its most violent form, unless the patient happen to be first carried off by paralytic symptoms; life, under these circumstances, never lasting any considerable time.

The cause of both these forms of amaurosis lies

in diseased alterations of the bones of the cranium, the dura mater, and the brain.

The morbid alterations of the bones of the skull mostly happen at its basis; and not only may caries take place, but still more frequently exostoses of various forms, which are sometimes so small that they are first detected by the bone giving the feel of a rough grater. At the same time they are so sharp, that if the finger be passed rudely over them, it will be painfully hurt. In these cases, the bones of the cavity of the skull are always found extremely thin; the diploe is almost entirely wanting, and the parietes of the orbit are preternaturally diaphanous, and, in some places, imperfect. Beer speaks of a lady's skull, who had been completely blind, and, for some weeks previously to her death, insensible; in which instance scarcely any part of the cavity of the skull could be touched without risk of the fingers being hurt by spicula. Once, in an amaurotic boy, who, for a short time before his death, was so insane that he used to devour his own excrement, Beer found at the side of the sella turcica a long considerable spiculum, which passed directly through the optic nerves at the place of their decussation. A case of amaurosis, produced by a spiculum of bone injuring the opposite side of the brain, is related by Anderson. (See *Trans. of the Society of Edinb.* vol. ii.) Sometimes the ethmoid bone has been found carious (*Ballonius, Paradigmata*, No. 7); sometimes other parts of the cranium. (*Mursinna, Beobacht.* b. i. No. 6; *Schmucker, Vermischte Schrift.* b. ii. p. 12.) Fractures of the skull at the anterior part of its basis may cause pressure on one or both optic nerves, or on their union, or may otherwise injure them. (See *Case in Sir B. Brodie's Paper on Inj. of the Brain*, in *Med. Chir. Trans.* vol. xiv.) These nerves may be variously affected by disease of the bone, or its membranous coverings, in the same situation; or, in the orbit, such disease may have a venereal origin, and be indicated by the simultaneous existence of other symptoms referrible to the same cause. (See *Lawrence on Dis. of the Eye*, ed. 3, p. 516; also *Case by Wilson*, in *Trans. of Soc. for Improvement of Med. and Chir. Knowledge*, vol. iii.) Sometimes the medullary substance of the brain itself is quite soft, while the cortical substance is full of blood-vessels, and unusually firm, the convolutions being hardly distinguishable.

Examples, in which the amaurotic blindness arose from abscesses in the brain, are reported by Ballonius (*Paradigmata Hist.* 7), by Pelargus (*Med. Jahrg.* b. iii. p. 198), Peyronie (*Mém. de l'Acad. Royale de Chir.* t. i. p. 212), Schaarschmid (*Berlin Nachrichten*, 1740, No. 26), Langenbeck (*Neue Bibl.* b. i. p. 61), and Mr. Travers (*Synopsis*, p. 143.) The latter author has recorded an instance in which a firm lardaceous tumour, of the size of a garden bean, situated on the same side as the blindness, compressed the optic ganglion and nerve at its origin from it. (*Synopsis*, p. 151.) I have seen a case of amaurosis, in which a medullary tumor as large as a middling-sized apple was found in the anterior lobe of the brain, attended with protrusion of the eye, and vast destruction of the bones. I was consulted in 1835, for a case of amaurosis in a young lady, 14 years of age, the daughter of a surgeon. The pupils were remarkably large, and of a clear black colour. She died suddenly, and a tumor, formed in the anterior lobe of the brain, was found to have been the

cause of the blindness and of her death. Mr. Travers has seen amaurosis produced by a medullary fungus of the brain. A case, occasioned by disease of the thalamus, is related by Villeneuve (*Journ. de Méd. continué*, 1811, Févr. p. 98); another, of a tumor of the thalamus on the same side as the blindness, is recorded by Ford (*Med. Commun.* vol. i. No. 4); and other swellings in various parts of the brain are described in *Ephem. Nat. Cur.* Dec. 3, Ann. 9, and 10, Obs. 253; *De Haen's Ratio Medendi*, P. 6, p. 271; *Journ. des Savans*, 1697; *Muzell's Wahrnehm.* b. ii. No. 13; *Plater, Obs. lib. i.* p. 108; *Thomann, Annalen für* 1800, p. 400, &c.; *Wardrop's Essays on the Morbid Anatomy of the Human Eye*, vol. ii. p. 174, &c.

Bonetus, in his *Sepulchretum Anatomicum*, lib. i. sect. 18, describes various cases which were quite incurable: after death the blindness in one instance was found to be occasioned by an encysted tumor, weighing fourteen drachms, situated in the substance of the cerebrum, and pressing on the optic nerves near their origin. In the second, the blindness was produced by a cyst, containing water, and lodged on the optic nerves, where they unite. In a third, it arose from a caries of the os frontis, and a consequent alteration in the figure of the optic foramina. In a fourth, the cause of the disease was a malformation of the optic nerves themselves. Mr. Lawrence refers to a specimen in Mr. Langstaff's museum, exhibiting the eyes, optic nerves, and part of the basis of the brain of a man, who had been amaurotic for twenty-eight years. The sclerotica, cornea, iris, pupil, choroid coat, and retina, are perfectly healthy. The optic nerves in their whole extent, from the globes backwards, are shrunk into white cords, not larger than a small crow-quill. At the point of union, they merely lie together without being joined, and each proceeds to its own side of the brain. Where they sweep round the crura cerebri, they are gradually confused and lost. (See *Lawrence on Dis. of the Eye*, ed. 3, p. 518.)

In some of the instances, in which no apparent alteration can be discovered in the optic nerve, the late Mr. Ware conjectured that a dilatation of the anterior portion of the circulus arteriosus of Willis may be the cause of the affection. The anterior part of the circulus arteriosus lies directly over, crosses, and is in contact with, the optic nerves; and just in the same way as the anterior part lies over the optic nerves, the posterior part lies over the nervi motores oculorum. Hence Mr. Ware attempted to refer the amaurosis itself, and the paralytic affection of the eyelids, and muscles of the eyes, sometimes attendant on the complaint, to a dilatation of the anterior and posterior branches of the circulus arteriosus. The frequently diseased state of the trunk, or small branches of the carotid arteries at the side of the sella turcica, is noticed by Dr. Baillie in his useful work on *Morbid Anatomy*, and he says the same sort of diseased structure is also found in the basilar artery and its branches. (See *Ware's Chir. Obs. on the Eye*.)

On the authority of Ecker, one case is upon record, where the cause of amaurosis depended upon an aneurism of the central artery of the retina. (*Pinel, Nosographie Philos.* t. ii. p. 122.)

Many of the causes of amaurosis are of such a nature as to render the disease totally incurable. Of this description is fungus hæmatodes, in which the structure of the retina and optic nerve is

changed in a remarkable manner, the whole cavity of the eyeball becoming filled with a substance resembling medullary matter, and the optic nerve changed in its form, colour, and structure. (See *Wardrop's Essays on the Morbid Anatomy of the Human Eye*, vol. ii. p. 156, 8vo. Lond. 1818.)

Injuries of the supra orbital branches of the fifth nerve have been frequently followed by loss of sight, and the experiments of Vicq d'Azyr, tend to prove the reality of amaurosis from the cause in question. Vicq d'Azyr exposed and lacerated the frontal and superciliary branches of the fifth pair in various animals, and found that the injury was followed by amaurosis. (*Journ. Compl. des Sciences Méd.* t. xlv. p. 201. Paris, 1832.)

According to Mr. Wardrop, it is only when this nerve is wounded or injured, and not divided, that amaurosis takes place; for the blindness may sometimes be cured by making a complete division of the trunk nearest its origin. (*Morbid Anatomy of the Human Eye*, vol. ii. p. 180.)

Dr. Hennen met with one or two cases of amaurosis from wounds of the supra-orbital nerve: the perfect division of the nerve produced at first no alleviation of the complaint, but after some time the eye partially recovered. (*Principles of Military Surgery*, p. 366.)

Irritation of other portions of the fifth nerve, from carious teeth or from tumors connected with, or pressing upon some of its branches, has been known to produce amaurosis, and in such cases removal of the irritating cause has generally been followed by restoration of the sight. Richter acquaints us with the case of a lady, who had been blind for years, but experienced a short recovery of her sight on having a tooth extracted. (*Anfangsgr. &c.* b. iii. kap. 14.)

A similar fact is recorded by Mr. Travers, who says, that he has seen an incipient functional amaurosis distinctly arrested by the extraction of a diseased tooth, when the delay of a similar operation had occasioned gutta serena on the opposite side two years before. (*Synopsis*, p. 299.)

Richter records the following example. A small shot pierced the upper eyelid, and lodged at the upper part of the right orbit, between the eyelid and eyeball, so that it could be felt externally. The patient shortly afterwards became blind in the left eye; but recovered his sight after the excision of the shot. (*Anfangsgr. der Wundarzn.* band iii. p. 439.)

In 1826, M. Magendie related to the French Academy of Sciences various facts exemplifying the remarkable influence of the fifth nerves over all the senses: and, with respect to the sense of sight, he finds that the action of the eyeball and optic nerve cease immediately they are completely deprived of the influence of those nerves. Thus, a state of the eye is produced that has the greatest analogy to amaurosis. Indeed, when the fifth nerves are divided in an animal, it is instantly bereft of sight on the side on which the nerve has been cut, notwithstanding the eye retains at the moment all the physical conditions necessary for vision. It is not to be supposed, however, that the fifth nerves perform the function usually referred to the optic ones. To *perceive the light*, and to *see*, as Magendie remarks, are, experimentally speaking, two different things. An animal, whose fifth nerves have been divided, does not see, neither is it conscious of the daylight, or of the strongest

artificial light; yet it decidedly perceives the impression of the rays of the sun, when they fall directly on the eye. Hence, a healthy, sound condition of the optic nerve on the one part, and of the fifth nerve on the other, is essential to perfect vision; and M. Magendie therefore deems it highly probable, that there are two kinds of amaurosis; one depending on a particular affection of the optic nerve, and retina; the other on disease of the fifth nerve, and the defect of its influence on the organ of vision. These reflections led him to make trial of a combination of acupuncture and galvanism for the cure of certain cases of amaurosis. Thus, in one case, having introduced one needle into the frontal nerve, and another into the upper maxillary one, he brought the needles into repeated contact with the two poles of a voltaic pile. In a fortnight, the patient had received considerable benefit from the plan. Other facts are also recorded in favour of this treatment. (See *Journ. Expér. de Physiol.* t. vi. p. 156 *et seq.*)

The abuse of narcotic poisonous substances may induce amaurosis; as opium, hyoscyamus, belladonna, &c. Lead will do the same thing. Dilatation and a fixed state of the pupil follow the mere application of some narcotics to the skin; a circumstance of which we take advantage in the treatment of several diseases of the eye; but it does not usually happen that belladonna and hyoscyamus, the substances employed in this way, produce any other effect than a degree of obscurity and dazzling, such as a great influx of light through a much dilated pupil might occasion. Taken internally, however, these and some other poisons of the same class, as stramonium, dulcamara, white hellebore, tobacco, opium, &c. cause more or less complete insensibility of the retina, along with mydriasis, or myosis. The blindness is often a very obstinate symptom, continuing a long while after disturbance of the intellectual functions has ceased. (See *Mackenzie on Dis. of the Eye*, p. 1064, ed. 4.)

An *amaurosis* is described as produced by certain vegetable *bitters*, and by particular articles of food. But the reality of such cases is doubted by Mr. Lawrence. (*Op. cit.* p. 491.)

Cat-eye amaurosis is a case particularly described by Beer; it rarely advances to complete blindness, and occurs chiefly in very old persons. Sometimes, however, it takes place in young subjects, and even in children. Beer alleges that it is always confined either to thin, dwindled, old gray-headed subjects, in whom the exchange of organic matter is carried on but tardily, or else to young subjects, who are unhealthy, and disposed to consumption, hectic adults, emaciated children, and as a consequence of severe injuries of the eye. While this amaurosis is not perfectly formed, the iris retains its mobility, and the pupil is neither preternaturally dilated nor contracted; but when once the patient is quite bereft of vision, the motions of the iris are slow, and the pupil larger than in a healthy eye in an equal degree of light. At the bottom of the eye, far behind the pupil, a concave pale gray, bright yellowish, or variegated reddish opacity, is developed. By this the eyesight is not merely weakened, but rendered quite confused, since all objects, and especially smallish ones, appear to be confounded together, particularly when the patient tries to inspect closely any determinate body. The further the disease

advances, the brighter and more visible is the bottom of the eye, the paler is the colour of the iris (a thing very conspicuous in dark-eyed persons); and when once the amaurosis is complete, so that no susceptibility of the impression of light is left, then, upon an attentive examination of the eye, one can mostly perceive, at the troubled deeper part of the eye, a slender vascular plexus, which merely consists of the ordinary ramifications of the central artery and vein. In a half-darkened place, such an eye presents a shining yellowish or reddish appearance, but only in certain positions of the eyeball; and in this respect, it is somewhat similar to the eye of a cat, whence Beer chooses to term the complaint cat-eye amaurosis. The disorder is also not accompanied with any other essential morbid appearances, except the decline of vision, or complete blindness. (*Lehre von den Augenkr.* b. ii. p. 496.) Beer, in fig. 1. tab. 4. of his second vol. has given, from nature, an admirable representation of this remarkable species of amaurosis. The differences in the appearances at the bottom of the eye, in this case, from those presented in the early stage of fungus hæmatodes of that organ, will be best understood by referring to the article FUNGUS HÆMATODES. On this point, however, I may here briefly state, that, in cat-eye amaurosis, there is *no projection*, but, on the contrary, a *concave depression* in the axis of vision. Cat-eye amaurosis may be known from incipient cataract, by the opacity being more deeply situated, and having a shining pearly lustre. (See *Journ. of Foreign Med.* vol. iv. p. 168.)

Beer observes, that the causes of this species of amaurosis are so obscure, that whatever is offered upon the subject can be received only as conjecture. A suspicion is sometimes entertained, that a deficiency of the pigmentum nigrum, and of the tapetum of the uvea, is concerned in the production of this form of blindness.

The prognosis cannot but be very unfavourable; for, as the surgeon is ignorant of causes, he cannot know what means ought to be adopted for their removal. It is fortunate, however, that this amaurosis rarely attains its highest degree, but almost constantly remains in the form of a more or less considerable amblyopia.

Just as little is yet known respecting any well-regulated mode of treatment; but the disease may sometimes be kept from getting worse, by the careful employment of such general remedies, regimen, and diet, as are calculated to improve the health. However, in the most fortunately managed cases, Beer never knew a step made towards the removal of the disease. (*Lehre von den Augenkr.* b. ii. p. 497, 498.)

PROGNOSIS OF AMAUROSIS.

In general, every amaurotic weakness of sight, and every completely formed amaurosis, are attended with the greatest probability of cure, where they began suddenly and were quickly developed. (Beer, *Lehre von den Augenkr.* b. ii. p. 454—456.) This observation perfectly coincides with the account given by Schmucker, who says that many of these suddenly formed cases fell under his notice, and were more easy of cure than when the disorder had come on in a more gradual way. (See *Vermischte Chir. Schriften*, b. ii.) It also agrees with what Mr. Travers has stated, namely, that

slow and steadily progressive cases of amaurosis are more to be apprehended in the result, that is, are less tractable, than either the sudden, or the rapidly advancing disease, supposing all to be alike free from unequivocal signs of organic change. (*Synopsis*, p. 298.)

Respecting suddenly produced cases, Mr. Lawrence holds out less encouragement than the preceding authorities. The prognosis, he says, is doubtful, and rather unfavourable than otherwise, as to the complete recovery of vision, if the affection, even in its most recent state, should have produced complete insensibility of the retina. He thinks we should speak doubtfully of the result in the case of complete insensibility to strong light, even if it had only lasted twenty-four hours. He considers it difficult to say in what number of days, or weeks, we should give up all hopes of recovery. In the supposed case of total insensibility, or even of a near approximation to it, there would be more ground for apprehension than hope, at the end of a week, though sight is sometimes restored under these circumstances; but the lapse of a few weeks, without improvement, makes the case hopeless.

If amaurosis be partial, and the case seen early, Mr. Lawrence says a complete cure may be expected. He thinks favourably of the event when amaurosis takes place in conjunction with chronic internal inflammation, or when it is evidently caused by active congestion in the head or eye; for that can be removed by suitable treatment. A similar judgment is delivered by Mr. Middlemore: when the case is recent, takes place in young persons, and is evidently produced by vascular plethora, he says the prognosis is favourable, because the remaining degree of vision proves that no important structural change has yet occurred, and the plethoric state of the system can be removed. (See *R. Middlemore on Dis. of the Eye*, vol. ii. p. 273.)

Dr. Mackenzie says, that "there is scarcely any disease in which the prognosis is, on the whole, so unfavourable as in amaurosis. It is only when the disease is not yet complicated with any material disorganisation, that amaurosis yields to treatment. But in the cases which do yield, the degree of the disease is not always slight, but often serious, and the attack is not always recent, but often of considerable standing. It is chiefly in cases of an inflammatory or congestive nature that the disease is overcome. (*On Dis. of the Eye*, ed. 4, p. 1030.)

When one eye has been completely bereft of sight by amaurosis, and the surgeon can find out little or no cause for the infirmity, there is strong reason for apprehending that the other eye will, sooner or later, become blind. To this fact the exceptions are rare.

According to Beer, the idea entertained by some writers is not built upon experience, that amaurotic patients, in whom the iris is still moveable, and the pupil not much dilated, are more easily and frequently cured than others in whom the iris is perfectly motionless and the pupil exceedingly dilated. For sometimes, during the treatment, or even spontaneously, the iris, after being quite immoveable, recovers its powers of motion, yet the patient may not, at the same time, regain the slightest degree of vision; and, on the other hand, many cases of perfect amaurosis are

cured without the iris recovering any of its mobility, and the pupil remains dilated during the remainder of the patient's life. (*Lehre von den Augenkr.* b. ii. p. 458.) Richter also states that an amaurosis may be cured which is attended with a pupil extraordinarily dilated and entirely motionless; and sometimes the disorder proves incurable, notwithstanding the pupil is of its proper size and capable of motion. The pupil sometimes recovers its moveableness, in the course of the treatment, although nothing succeeds in restoring the eyesight. (*Anfangsr. der Wundarzn.* b. iii. p. 424, 8vo. Gött. 1795.) However, the continuance of the perfect mobility of the pupil is set down by Mr. Middlemore as a favourable symptom; but he would not pronounce a case hopeless in which its mobility is entirely lost. (See *Middlemore on Dis. of the Eye*, vol. ii. p. 262.)

In some rare instances, amaurotic blindness has been cured by some apparently accidental, or indeed morbid effect, without any assistance from art; by hemorrhage from the nose, an intermittent fever, a blow on the head, &c. Beer operated successfully upon both eyes of a patient with cataracts, which had been previously depressed too far against the retina, so that their pressure gave rise to amaurosis, which, after continuing eight years, was suddenly removed by the patient's accidentally falling out of bed, and pitching upon the top of his head. (*Lehre von den Augenkr.* b. ii. p. 458.)

The following observations, made by Beer respecting the prognosis, cannot fail to prove interesting. There is a species of amaurosis which gradually diminishes of itself; for instance, that which arises from hard drinking, or the effect of narcotic poisons, belladonna, opium, hyoscyamus, &c.

Sometimes imperfect amaurosis goes away without any assistance from art, in consequence of the accession of some other disease, as an eruption, a discharge of matter from the ear, bleeding from piles, return of the menses, &c.

In most cases, when the surgeon is so fortunate as to cure amaurosis, there still continues, for life, a considerable degree of amblyopia, more especially if the amaurosis has been complete.

Sometimes by successful treatment, vision is in a great measure, or even entirely, restored in one eye, yet the other remains completely blind; or one eye sees again much sooner than its fellow, although they were both affected together with an equal degree of blindness.

It often happens that, though a material degree of vision returns in the course of the treatment, the faculty is restricted to a circumscribed point of the retina, so that the patient is enabled to see objects plainly only when they are held in a particular direction before him; while, in other directions, they are either quite invisible, or very indistinct. (Beer, *Lehre von den Augenkr.* b. ii. p. 459, 460.)

Amaurosis, following an injury of the supra-orbital nerve, ordinarily resists every endeavour made to relieve it, and this whether it come on directly after the blow, or some weeks subsequently to the healing of the wound of the eyebrow; but it is not always incurable. One cure is recorded by Valsalva. (*Dissert.* 2, § 11.) Additional instances are reported by Hey (*Med. Obs. and Inq.* vol. v.); by Larrey (*Mém. de Chir. Militaire*, t. iv. p. 181.)

Mr. Hennen and Mr. Wardrop both mention instances in which complete division of the trunk of the nerve on the side nearest to its origin has been followed, in some cases, by complete cure, and in others by a partial restoration of the sight.

Perfect, inveterate amaurosis, attended with organic injury of the substance constituting the immediate organ of sight, says Scarpa, is a disease absolutely incurable. *Imperfect, recent amaurosis*, particularly that which is *periodical*, is usually curable; for it is mostly dependent upon causes which, though they affect the immediate organ of sight, are capable of being dispersed, without leaving any vestige of impaired organisation in the optic nerve or retina.

When amaurosis has prevailed several years in persons of advanced age, whose eyesight has been weak from their youth; when it has come on slowly, at first with a morbid irritability of the retina, and then with a gradual diminution of sense in this part, till total blindness was the consequence; when the pupil is motionless, not circular, and not much dilated; when it is widened in such a degree that the iris seems as if it were wanting, and the margin of this opening is irregular and jagged; and when the bottom of the eye, independently of any opacity of the crystalline lens, presents an unusual paleness, like that of horn, sometimes partaking of green, and reflected from the thickened retina, the disease may be generally set down as incurable. Kieser joins Scarpa in representing this alteration as an unfavourable omen, adding, that it only takes place in examples of long standing, and that, when it is considerable, the disease is incurable. Langenbeck differs, however, from both these authors, and particularly from Kieser, assuring us, not only that he has often seen this discoloration of the bottom of the eye in the early stage of amaurosis, but seen patients in this state soon cured. The cases which he has published, in proof of this statement, I have read with care, and find them completely satisfactory. Langenbeck agrees with other writers in imputing the appearance to a morbid change of the retina, and the treatment which he prescribes consists in the internal exhibition of the oxymuriate of mercury in small doses, and friction with mercurial ointment on the eyebrow and temple. (See *Langenbeck's Neue Bibl. für die Chirurgie*, b. i. p. 64—69, &c. Göttingen, 1815.)

Cases, attended with pain all over the head, and a continual sensation of tightness in the eyeball; or preceded by a violent, protracted excitement of the nervous system, and then by general debility, and languor of the constitution, as after masturbation, premature venery, and hard drinking; or connected with epileptic fits, or frequent spasmodic hemicrania; or which are the consequence of violent, long-continued, internal ophthalmia, may be set down as incurable. Nor can any cure be expected, when amaurosis proceeds from a direct blow on, or violent concussion of the eye; foreign bodies in the eyeball, or exostoses about the orbit; or when it is conjoined with a manifest change in the figure and dimensions of the eyeball. The same judgment is applicable to complete amaurosis from long exposure of the eye to vivid light, or to causes which have been protracted in their injurious effects upon the retina. (See *R. Middlemore*, vol. ii. p. 274.)

Recent, sudden cases, in which the pupil is not

excessively dilated, and its circle remains regular, while the bottom of the eye is of a deep black colour; cases unaccompanied with any acute continual pain in the head and eyebrow, or any sense of constriction in the globe of the eye itself; cases which originate from violent anger, deep sorrow, fright, gastric disorder, general plethora, or the same partial affection of the head, suppression of the menses, habitual bleedings from the nose, piles, &c., great loss of blood, nervous debility, not too inveterate, and in young subjects, are generally curable. Amaurosis is also mostly remediable, when produced by convulsions or the efforts of difficult parturition; when it arises during the course, or towards the termination of acute or intermittent fevers; and when it is periodical. (*Scarpa, Osservazioni sulle Malattie degli Occhi*, cap. 20. Venez. 1802.) If amaurosis take place from the free administration of mercury, from protracted suckling, from profuse diarrhoea, or from a state of general debility, induced by other causes, the prognosis must depend upon our capacity to remove the debilitated state of the constitution, or its causes. In some cases, this is easy; in others, impossible. (See *R. Middlemore*, op. cit. vol. ii. p. 273.)

According to Mr. Travers, it is rather the degree than the nature and origin of the symptomatic functional amaurosis that should in most cases influence our prognosis; yet the latter circumstances, it is equally clear, afford more or less encouragement, in proportion as the pre-existing states of disease ordinarily admit of relief, or not. Thus, says he, the amaurosis from gastric diseases, from plethora, from irritation, are all of them relievable, and, if treated at an early period, remediable. Whereas paralysis, the sequel of fever, or of epilepsy, or severe constitutional diseases, whether acute or chronic, or depending upon habitual cerebral congestions combined with organic visceral disease, or induced by the operation of noxious agents on the system, is a hopeless form of the malady. (*Synopsis*, p. 296.) I may remark, however, that various examples of recovery from amaurosis induced by fevers have fallen under my own notice.

In general, when the treatment proves successful, the return of vision is accompanied with a regression of the same characteristic effects which were disclosed in the gradual advance of the disorder, viz. appearances as if there were before the eyes flashes of light, a cobweb, network, mist, or flaky substances. (*Beer, Lehre von den Augenkr.* b. ii. p. 460. Wien. 1817.)

Upon the commencement of the cure, there is also a return of the obliquity of sight; one of the most constant symptoms of imperfect amaurosis. This is a circumstance which Hey took particular notice of: he says, that it was most remarkable in these persons who had totally lost the sight in either eye; for in them the most oblique rays of light seemed to make the first perceptible impression upon the retina; and, in proportion as that nervous coat regained its sensibility, the sight became more direct and natural. (See *Med. Obs. and Inq.* vol. v.)

TREATMENT OF AMAUROSIS.

When amaurosis is to be fundamentally cured, not upon empirical, but scientific principles, all the causes of the disorder must be ascertained, and, if

possible, removed, as in the treatment of every other complaint. How often, however, it is impossible to accomplish either the one or the other of these objects, must be clear enough from the preceding observations. Amaurosis is sometimes merely a symptom of another disease, and then attention must be directed to the primary malady, as illustrated in apoplexy, hydrocephalus, depressed fractures of the skull, and disorder of the intestinal or uterine functions.

If no particular circumstance can be assigned as the cause of amaurosis, the surgeon should act with great caution, and constantly bear in his mind, first, the constitution, sex, and age of the patient; secondly, his ordinary employments, and general mode of living; and thirdly, the principal morbid appearances under which the disease originated and was developed. (*Beer, Lehre von den Augenkr.* b. ii. p. 462.)

In that species of amaurosis which arises from causes inducing the disease, by means of a preternatural fulness and dilatation of the blood-vessels of the brain, or eye, the indication is to lessen the quantity of blood and general plethora, and determination of blood to the head and organ affected. For this purpose the patient may be bled in the arm or temporal artery. The evacuation is to be repeated as often as seems necessary, and it will be better to begin with taking away from sixteen to twenty ounces. The efficacy of bleeding, in the cure of particular cases, is strikingly exemplified by numerous well-authenticated observations. Richter informs us of a woman who, on leaving off having children, lost her sight; but recovered it again by being only once bled in the foot. A spontaneous hemorrhage from the nose also cured a young woman who had been blind for several weeks. (*Anfangsgr. der Wundarzn.* b. iii. p. 442.)

That bleeding is sometimes hurtfully and wrongfully practised in amaurotic cases, is a fact which admits of no doubt. Mr. Travers particularly refers to one description of cases where the lancet does harm: these are cases of undue determination of blood to the organ, which are especially common after deep-seated chronic inflammation or distress from over-excitement, by which its vessels have lost their tone; an effect decidedly increased by depletion. In one interesting case of this kind a gradual, but perfect, recovery followed a regulated diet, and a course of the blue pill, with saline aperients. (*Synopsis*, p. 159.) All cases of direct debility and proper paralysis of the retina (says Mr. Travers) are aggravated by loss of blood, and the great prevailing mistake in the treatment of amaurosis is the indiscriminate detraction of blood. (*Synopsis*, p. 303.)

When, in addition to general bleeding, topical is also necessary, leeches may be applied to the temples, or cupping glasses to the back of the neck, or temples. Besides bleeding, purgatives, blisters, bathing the feet in warm water, low diet, repose of the organs, &c. are proper.

In some cases the foregoing means fail in producing the desired benefit, even when followed up, as far as the pulse and strength will allow. Here the continuance of the disease may depend, either upon the stoppage of some wonted evacuation of blood, or else upon some other cause of the first class. In the first of these cases (says Richter) experience proves that the disease will sometimes not give way before the accustomed discharge is

re-established. A woman, who (as this author acquaints us) had lost her sight, in consequence of a sudden suppression of the menses, did not recover it again till three months after the return of the menstrual discharge, notwithstanding the trial of every sort of evacuation. He also tells us of another woman, who had been blind half a year, and did not menstruate, and to whose external parts of generation leeches were several times applied. As often as the leeches were put on (says Richter) the menses in part recommenced; and, as long as they made their appearance, which was seldom above two hours, the woman always enjoyed a degree of vision. (*Anfangsgr. der Wundarzn.* b. iii. p. 443.)

For the amaurosis arising from suppression of the menses, Scarpa recommends leeches to the pudenda, bathing the feet in warm water, and afterwards exhibiting an emetic, and laxative pills, made of rhubarb and tartrate of antimony, combined with gummy and saponaceous substances. If these means fail in establishing the menstrual discharge, he says great confidence may be placed in a stream of electricity, conducted from the loins across the pelvis, in every direction, and thence repeatedly to the thighs and feet.

For the amaurosis proceeding from the stoppage of habitual bleeding from piles, Scarpa recommends leeches and fomentations to the hemorrhoidal veins, then an emetic, and afterwards the same opening pills. (*Osservazioni sulle principali Malattie degli Occhi*, cap. 19.)

The principle on which Mr. Lawrence directs the treatment, is that of putting a stop to vascular excitement, with the view of preventing the permanent injury of altered structure and impaired function of the retina. Hence he is a zealous advocate for the antiphlogistic treatment in the early stage of amaurosis. "But," says he, "if this treatment be not found to remove the change which has been produced in the retina, we must have recourse to mercury, which appears to be as decidedly beneficial in these cases as in iritis or general internal inflammation. The remark which I made respecting the use of mercury in those affections, applies also to the present case, namely, that its good effect mainly depends upon the promptitude with which it is employed. The alterative form is insufficient; we give it with the view of arresting inflammation in the structure, which is the very seat of vision; that structure is easily changed by the inflammatory process; our only remedy is to push the mercury in a decided manner, and if we do so, we shall put a stop to the affection." When the amaurotic affection depends on vascular plenitude of the retina, and that peculiar action of its capillary system of vessels which is disposed to bring on organic changes, Mr. Middlemore is also an advocate for mercury, which, for the purpose of stopping such action and producing an absorption of effused or deposited matter, he directs to be employed freely, so as to affect the mouth. But, he observes, if the amaurotic symptoms are not at all relieved when the gums have become sore, its use is not to be continued: on the contrary, if any improvement occur, the constitution should be kept under the influence of mercury by the administration of two grains of the submuriate with a small quantity of opium, once or twice a day. (*R. Middlemore on Dis. of the Eye*, vol. ii. p. 277.) Instead of discontinuing mer-

cury, if no amendment take place directly the gums are sore, he advises the patient to be kept at least two or three weeks well under the influence of the medicine; for, unless this be done, it has not had a fair trial. When the antiphlogistic treatment, and a fair trial of mercury have failed, Mr. Lawrence contents himself with recommending such management as is most conducive to general health; as a residence and frequent exercise in a pure air; plain nutritious diet; mild aperients, with the occasional use of an active purgative; and repose of the affected organ. He mentions also a trial of a seton, or repeated blisters behind the ears, or at the side or back of the neck. As already stated, however, he does not wish it to be supposed that all amaurotic patients require to be bled and salivated. Amaurosis, he says, often comes on in a slow and very insidious manner in persons of enfeebled constitution; the organ suffers from habitual excessive exertion at the same time that the general powers are depressed by residence in confined dwellings, bad air, sedentary occupations, unwholesome diet, costiveness, and the other injurious influences of such causes. If we should see a thin, pallid, and feeble woman, who had destroyed her health by close confinement to needle-work, and whose eyes were beginning to fail, the same active measures would by no means be admissible. We should empty the alimentary canal, perhaps take a little blood by cupping, or by leeches to the temples, and then use mercury in the alterative form, together with mild aperients. A few grains of Plummer's pill may be given every night, or every second night, and the bowels may be kept open with electuary, castor oil, or rhubarb and magnesia, taken occasionally. The blue pill may be taken in combination with aloes or colocynth. It may be necessary, says Mr. Lawrence, to persevere with the mercury, slowly increasing the dose until a slight influence is visible in the mouth. A nutritious but temperate diet, good air and exercise, and repose of the affected organ, are important auxiliaries, and a succession of moderate sized blisters may be advantageously combined with these means. Thus, observes Mr. Lawrence, the same principles regulate our treatment; but it is modified in degree, according to the violence of the symptoms, and the patient's strength. In the latter description of cases, after mild antiphlogistic means and clearing the alimentary canal, he admits that it may be expedient to combine tonics with aperients, or rhubarb with bark, calumba, or cascarrilla; and to allow a little porter and wine.

One case of temporary palsy of the retina from over-excitement, mentioned by Mr. Travers, yielded to blistering the forehead, and a gentle salivation excited by calomel joined with opium. (*Synopsis*, p. 164.) Another case, brought on by the use of telescopes and sextants, gave way to a copious bleeding, brisk purging with jalap and calomel, blisters to the temples, and a course of mercury. (*Op. cit.* p. 166.)

When the disease does not originate from the stoppage of any natural or habitual discharge of blood, and does not yield to the evacuating plan, Richter thinks the surgeon justified in concluding that the paternaturally dilated vessels have not regained their proper tone and diameter, and that topical corroborant remedies, particularly cold water, ought to be employed. In this kind of case, he is an advocate for washing and bathing

the whole head with cold water, especially the part about the eyes; a method, he says, which may often be practised, after evacuations, with singular and remarkable efficacy.

When amaurosis follows the healing of old sores, Beer recommends the formation of them again, by applying to the cicatrix strong mustard cataplasms, and the muriate of soda; and, if the new ulcers cannot be made to discharge properly, he recommends issues on the legs or thighs. These plans are to be aided by such medicines as act specifically upon the skin, like antimonials, especially the sulphur auratum antimonii. Beer also speaks favourably of sulphur baths; and, in cases complicated with debility, administers tonics. (See *Lehre von den Augenkr.* b. ii. p. 556—563.) When amaurosis has followed the sudden healing of ulcers, or the disappearance of an eruption, or the suppression of some customary evacuation, Mr. Middlemore is an advocate for counter irritation by means of a seton or issue. (*On Dis. of the Eye*, vol. ii. p. 279.)

In the incomplete amaurosis from general nervous debility, copious hemorrhage, convulsions, and long-continued intense study, especially by candlelight, Scarpa advocates the following plan of treatment. When the complaint is recent, in a young subject, the alimentary canal is to be emptied with small repeated doses of rhubarb, after which tonic cordial remedies are to be given. At the same time, the patient is to abstain from everything that has a tendency to weaken the nervous system, and, consequently, the eyesight. After emptying the stomach and bowels, it is proper to prescribe the decoction of bark with valerian, or the infusion of quassia with the addition of a few drops of sulphuric æther to each dose, with nourishing, easily digestible food. The aromatic spirituous vapours (mentioned in the article OPTHALMIA) may then be topically applied; or, if these prove ineffectual, the vapour of liquor ammoniæ. The patient must take exercise on foot, horseback, or in a carriage, in a wholesome dry air, in warm weather, and avail himself of sea-bathing. He must avoid all thoughts of care, and refrain from fixing his eyes on minute shining objects. The impression of vivid light on the retina is to be moderated by means of flat green glasses. (*Saggio di Osservaz.* cap. 19.)

Mr. Travers remarks, that the amaurosis from depletion is sometimes mistaken for the opposite case, viz. that from plethoric congestion: this is owing to the coincidence of a dilated and immoveable pupil, muscæ, and a deep-seated pain in the head, with occasional vertigo, and its frequent occurrence in a corpulent habit. By a cautious use of tonics (says Mr. Travers) it is relieved; by whatever lowers, or stimulates, whether diet or medicine, it is decidedly aggravated. In this form of amaurosis, vision is further enfeebled by the loss of as much blood as flows from two or three leech bites. (*Synopsis*, &c. p. 160.)

When the weakness is confined to the eye, Richter thinks corroborant applications alone necessary. Bathing the eye with cold water, says he, is one of the most powerful means of strengthening the eye. The patient should dip in cold water a compress, doubled into eight folds, and sufficiently large to cover the whole face and forehead, and this he should keep applied as long as it continues cold. Or else he should frequently

apply cold water to his eyes and face with his hand, on a piece of rag.

The eye may also be strengthened by repeatedly applying blisters of a semi-lunar shape above the eyebrows, just long enough to excite redness. Richter likewise speaks favourably of rubbing the upper eyelid, several times a day, with a mixture of the tinctura lyttæ and spiritus serpilli. (*Anfangsgr. der Wundarz.* b. iii. p. 452.)

Here the endermic application of strychnia deserves to be remembered.

In the amaurosis suddenly formed by exposure to vivid light or lightning, we may clear out the alimentary canal with an active dose of calomel and jalap. Blisters may then be applied above the eyebrows; and if these fail, electricity, or the external use of strychnia, may be tried. (See *Middlemore on Dis. of the Eye*, vol. ii.)

The employment of electricity in amaurosis was advocated by Mr. Hey, and also by Mr. Ware, and there seems to be sufficient ground for believing that in some cases it has proved highly serviceable. Mr. Ware thought it likely to be especially useful in the amaurosis from the effect of lightning.

Magendie says that he has seen great benefit resulting from its use, and in some cases of incomplete amaurosis that it produced a perfect cure.

The method employed by him was that of galvanopuncture. He inserted needles into the frontal and superior maxillary nerves, and then passed a galvanic current along them.

Mr. Lawrence on the other hand considers the indiscriminate use of electricity both ineligible and unsafe, and especially dangerous whenever congestion exists in the head, or active determination in the eye. He thinks it should only be used as an empirical remedy, after other measures have failed. (Ed. 3, p. 559.)

Dr. Mackenzie, too, says that "electricity, galvanism, and electro-magnetism are likely to be useful only in cases of a torpid character, and free from excitement, and that they would be hazardous if inflammation were present, or if they excited pain." (*On Dis. of the Eye*, ed. 4, p. 1034.)

In amaurosis from the gradual effect of any exposure of the eye to vivid light, or of hard study by light of lamps or candles, the foregoing treatment would I think be less likely to answer. Here the symptoms depend upon congestion or inflammation affecting the retina and optic nerve, and perhaps even the cerebral portion of the optic apparatus. The treatment, therefore, should consist of moderate depletion, followed by mercury and counter irritation, and the most perfect rest of the organ. (*Mackenzie on Dis. of the Eye*, ed. 4, p. 1059.)

We come now to the consideration of that species of amaurosis which is regarded as the effect of some unnatural irritation. Here, according to the precepts delivered by Richter, we should endeavour to discover what the particular irritation is, and then endeavour to effect its removal. Sometimes the irritation is both discoverable and removable, and still the blindness continues. In this circumstance, Richter thinks that the surgeon should endeavour to obviate the impression which the irritation has left upon the nerves, by the use of anodynes; or else try to remove the torpor of the nerves by stimulants. Now, according to Schmucker, Richter, and Scarpa, curable imperfect amaurosis commonly depends on some disease, or

irritation in the gastric system, complicated with general nervous debility, in which the eyes participate. Hence it appears to them that the chief indications are, to free the alimentary canal from all irritating matter, improve the state of the chylipoietic viscera, and invigorate the nervous system in general, and the nerves of the eye in particular.

For an adult, Scarpa directs three grains of antimonium tartarizatum to be dissolved in four ounces of water, and a spoonful of this solution to be given every half hour, until pausea and copious vomiting are produced. The next day some opening powders are exhibited, consisting of an ounce of the super-tartrate of potash, and one grain of antimonium tartarizatum, divided into six equal parts. The patient takes one of these three times a day, for eight or ten days in succession. If the patient, during their use, should make vain efforts to vomit, the emetic, as at first directed, is to be prescribed again, and repeated a third and fourth time, should it be deemed necessary.

The stomach having been thus emptied, he orders an aperient pill, composed of rhubarb and tartarised antimony to be taken night and morning, for a month or six weeks.

When the state of the stomach has been improved, and the restoration of sight partly effected, such remedies must be employed as strengthen the digestive organs, and excite the vigour of the nervous system in general, and of the nerves of the eye in particular. With this intention, Scarpa prescribes bark and valerian in powder, with nourishing diet, with a moderate quantity of wine, and proper exercise in a salubrious air. For exciting the action of the nerves of the eye, the vapour of liquor ammoniæ, properly directed against the eye, he says, is of the greatest service. This remedy is applied by holding a small vessel, containing it, sufficiently near the eye to make this organ feel a smarting, and to cause a copious secretion of tears, and a redness, when it is proper to stop, and repeat the application three or four hours afterwards.

The operation of these vapours may be promoted by other external stimulants, such as blisters to the nape of the neck; friction on the eyebrow with the anodyne liquor; the irritation of the nerves of the nostrils by sternutative powders, like that composed of two grains of turbeth mineral, and a scruple of powdered betony leaves; and, lastly, electricity. The external use of strychnia would here deserve trial in the manner presently specified. The imperfect amaurosis, suddenly brought on in consequence of the body being excessively heated, or of exposure to the sun, or by violent anger, in plethoric subjects, requires general and topical evacuations of blood, and the application of cold washes to the eyes and whole head. Scarpa then prescribes an emetic, and afterwards antimonial purgatives. By means of bleeding and an emetic, Schmucker often restored the eyesight of soldiers, who had lost it in making forced marches. In amaurosis suddenly occasioned by violent anger, an emetic is the more strongly insisted upon after bleeding, as the blindness thus arising is always attended with a bitter taste in the mouth, tension of the hypochondria, and continual nausea. Richter mentions a clergyman, who became completely blind, after being in a violent passion, and whose eyesight was restored the very next day, by means of an emetic, given with the view of relieving some obvious marks of bilious disorder.

In this country, this free use of tartarized antimony, which has proved so efficacious on the Continent, has not been found to answer. Mr. Travers states, that he does not recollect an instance of decided benefit from it, though he has often tried it fairly. He agrees, however, in the indication, as he remarks, that the removal of an irritating, or oppressing cause, will often effect a sudden and marked relief, as by clearing the intestinal canal of vitiated secretions, restoring the digestive functions, or taking away blood where the necessity is indicated. In gastric cases, for which emetics have been particularly recommended, he prefers a long-continued course of the blue pill, with gentle saline purgatives, and tonic bitters. (*Synopsis*, p. 299—304.)

Beer is another high authority against the use of emetics, even in the amaurosis from disorder of the gastric organs. Emetics, which never operate without some violence, he says, are to be most carefully avoided in plethoric individuals, or those who have a manifest determination of blood to their heads and eyes, or any acceleration of the circulation. The caution here given must be observed, even though emetics may on other accounts seem advisable; and, according to Beer, the determination of blood and the state of the system here mentioned are commonly attendant upon this species of amaurosis. Indeed (notwithstanding the testimony of Schmucker, Richter, and Scarpa, in favour of emetics), Beer positively affirms that the violent operation of an emetic frequently converts this sympathetic amaurotic weakness of sight into complete blindness. Although I apprehend that Beer may here be somewhat prejudiced against emetics, candour obliges me to add, that, in this country, their efficacy in the present disease is by no means equal to the representations of Richter and Scarpa. When there is less tendency to vomiting, but the case is attended with an oppressive sense of weight about the stomach, frequent eructations, an inflated belly, tense hypochondria, and confined bowels, Beer found that clysters and tolerably brisk purgatives were always of the greatest service, both in regard to the general complaints, and the amaurotic weakness of sight; the removal of the offensive matter from the alimentary canal being immediately followed by a cessation of the determination of blood already mentioned. Lastly, when this amaurosis originates altogether from the presence of worms in the bowels, common anthelmintics are to be prescribed. In all these cases, says Beer, mere local treatment is quite inapplicable, and may do mischief. (*Beer, Lehre von den Augenkr.* b. ii. p. 517—521.)

In *periodical amaurosis*, attended with serious impairment or loss of vision, returning daily, weekly, or monthly, or at irregular intervals, the eye being little or not at all affected in the intermediate periods, the best means of cure are bleeding, purgatives, and counter irritation. This treatment is especially applicable to hemeralopia.

In *amaurosis excited by dentition*, the gums may be divided, mild laxatives and small doses of syrup of poppies given, and the child put into a warm bath. If amaurosis depend upon the irritation of a carious tooth, this should be extracted.

For *amaurosis from a partial wound, or laceration of the supra-orbital nerve*, the best plan is to make a free division of it.

Of late, strychnia has been employed as a remedy

for amaurosis. It seems to Mr. Middlemore that its use should be confined to cases in which the retina is in a state of atony from some cause acting *directly* upon its texture, or upon its texture through the medium of the general debility of the system. At all events, he is of opinion, that it should not be resorted to when there is much vascular fulness either of the system, or the retina, or a tendency to inflammation. Its effects are likewise to be most carefully watched. An atonic state of the retina, or of some part of the nervous apparatus of the eye, productive of amaurosis, when unconnected with a full plethoric habit of body, determination of blood to the head, or any tendency to apoplexy, or any structural change either in the retina, or its immediate nervous relations, may be treated by means of strychnia, particularly if tonics and general stimulants have been already unsuccessfully tried. The bowels are to be first freely opened, and aperient medicine occasionally given during the use of strychnia. Mr. Middlemore puts a narrow blister above the eyebrow of the affected eye, or above each eyebrow, if both eyes are involved; and after the cuticle and serum have been removed, sprinkles a small quantity of strychnia upon the raw surface, commencing with the fourth of a grain upon each side. If vision be not improved, this quantity may be gradually increased to two grains; the part is also dressed with savine cerate. The strychnia is applied only once in twenty-four hours, and the eyebrow is preferred as the place for its action, on account of the probable special effect of the strychnia upon the supra-orbitary nerve, in addition to its other more general influence. If strychnia excite great local uneasiness, it may be blended with a little flour, or powdered opium. Mr. Middlemore observes, that if the patient should become sensible of occasional flashes of light before the eye, soon after the commencement of this treatment, there would be great encouragement to persevere; but that if vision should be not at all influenced, or improved, after the strychnia had been tried a fortnight in sufficiently powerful but not imprudent quantities, it ought to be discontinued. Strychnia appears to him to be well adapted to the case of miners, whose eyes are affected with incomplete amaurosis, and who have been accustomed to follow their employment by means of a very feeble light; and also to cases of impaired sensibility of the retina, occasioned by too great a delay in curing congenital cataract. (See *Middlemore on Dis. of the Eye*, vol. ii. p. 282.)

Strychnia has also been prescribed as an internal remedy for amaurosis.

A more extended experience has not shown that strychnine deserves to occupy any very prominent place as a remedy for amaurosis; Mr. Tyrrell says that he has frequently tried it in the cases that appeared to him most appropriate, but that he had not seen one single instance of benefit from its employment, although he had persevered till alarming muscular contractions were produced. He considers further that serious mischief has resulted from its indiscriminate use. And Mr. Lawrence states that his opinion coincides with that of Mr. Tyrrell, with reference not only to strychnia, but also to veratria, which he has found equally inefficacious. (*On Dis. of the Eye*, ed. 3, p. 565.)

Dr. Mackenzie, after mentioning that it has been given, as well as a host of other drugs of similar

properties, in the hope that they might produce some stimulating effect on the nerves of sense, states his opinion that it is extremely doubtful if they have ever been productive of the least good effect (*On Dis. of the Eye*, ed. 4, p. 1033), and Mr. Dixon says that "its action appears to be so precisely limited to the motory fibres of the nervous system, that to expect it to influence a nerve of special sense, is to confound all our notions of nervous physiology." In no case of impaired or lost vision has he seen it effect the slightest improvement. (*Practical Study of Dis. of the Eye*, 1855, p. 189.)

AMBE (from ἄμβη, the projecting edge of a rock). An old surgical machine for reducing dislocations of the shoulder, and so called because its extremity projected like the prominence of a rock. Its invention is referred to Hippocrates. The ambe is the most ancient mechanical contrivance for the above purpose; but it is not at present employed. Indeed, it is scarcely to be met with in the richest cabinets of surgical apparatus. It is composed of a piece of wood, rising vertically from a pedestal. With the vertical piece is articulated, after the manner of a hinge, a horizontal piece, with a gutter formed in it, in which the luxated limb is laid and secured with straps. The patient places himself on one side of the machine; his arm is extended in the gutter, and secured; the angle, formed by the union of the ascending piece, and by the horizontal branch, is lodged in the armpit, and then the horizontal branch is depressed. In this way extension is made, whilst the vertical part makes counter-extension, and its superior part tends to force the head of the humerus into the articular cavity. But there is nothing to fix the scapula, and the compression made by the superior portion of the

vertical piece of the machine tends to force the head of the humerus into the glenoid cavity, before it is well disengaged by the extension.

AMBLYOPIA (from ἀμβλῦς, dull, and ὤψ, the eye). Hippocrates means by this word, in his Aph. 31, sect. 3, the dimness of sight to which old people are subject. Modern writers generally understand by amblyopia incomplete amaurosis, or the weakness of sight attending certain stages and forms of this disorder.

AMMONIÆ MURIAS, AMMONIÆ HYDROCHLORAS. *Sal Ammoniac.* Its chief use in surgery is as an external discutient application. (See *Lotio Ammon. Muriatæ cum Aceto.*)

Mr. Justamond recommends the following application to milk-abscesses: ℞ Ammoniac Muriatis ʒj. Spiritus Roris marini lb. j. Misc. Linen rags, wetted with the lotion, are continually applied to the part affected. There can be little doubt of the utility of this lotion in dispersing the induration left after mammary abscesses; but while these cases are accompanied with much pain, tension, and inflammation, emollient fomentations and poultices are to be preferred. For rubefacient purposes, pure ammonia is extracted from the decomposition of muriate of ammonia by means of the soda contained in soap. A plaster is made by combining ʒj. of soap with ʒij. of common litharge plaster; and when nearly cold, adding ʒj. of muriate of ammonia in fine powder. From this nearly ʒj. of ammonia in a pure state is slowly evolved, and exerts its action on the skin. (See *A. T. Thomson's Elem. of Materia Med.* p. 957, ed. 2.)

If muriate of ammonia be mixed with its weight of powdered nitre, and dissolved in six or eight parts of water, it produces a very cold lotion, which may be used, as a substitute for ice, in cases of strangulated hernia.

AMPUTATION. The operation of cutting off a limb, or other part of the body, as the breast, penis, &c.

Such an operation frequently becomes indispensably proper, on the principle of sacrificing a branch, as it were, for the sake of taking the only rational chance of saving the trunk itself. Indeed, the suggestion of this measure, in cases of mortification, where there is no chance of the parts recovering, may be said to be derived from nature herself, who, by a process to which I shall advert in speaking of *mortification*, detaches the dead from the living parts; this separation is followed by cicatrization, and the patient recovers.

The necessity for amputation has always existed, and ever will continue, so long as the destructive effects of injuries and diseases of the limbs cannot be obviated in any other manner. As Graefe observes, there was once a period when the operation was more frequently practised than at present, and this fact is to be imputed less to the caprice of surgeons than to the imperfection of the means which used to be employed for the relief of local diseases. For then, aneurisms of the limbs, and some other cases, at present treated with success, were always deemed incurable without amputation.

As the author of another valuable modern work has said, it is an excellent observation founded on the purest humanity, and justified by the soundest professional principles, that to *save one limb is infinitely more honourable to the surgeon, than to have*

performed numerous amputations, however successful; but it is a remark fully as true, that it is much better for a man "to live with three limbs than to die with four." (*Hennen on Military Surgery*, p. 251, ed. 2.) To this should be added the reflection, that some unfortunate beings have been known to submit to the loss of all their legs and arms, and yet recover. In the Hôtel des Invalides at Paris, mutilated objects are in recollection, who had lost all their thighs and arms, so that, unless assisted, they could not stir, and it was necessary to feed and wait upon them, like new-born infants. (*Morand. Opusc. de Chir.* p. 183; and *Graefe*, op. cit. p. 23.)

The amputation of limbs was anciently practised under many disadvantages. The best way of making the incisions was unknown; the ignorance of the old surgeons about the right method of stopping hemorrhage was the death of a large proportion of the patients who had courage to submit to the operation; the mode of healing the wound by the first intention was not understood, or not duly appreciated; and the instruments employed were as awkward and clumsy as the dressings were irritating and improper.

Modern practitioners have materially simplified all the chief operations in surgery: an object which has been accomplished, not merely by letting anatomical science be the main guide of their proceedings; not simply by devising more judicious and less painful methods; not only by diminishing the number, and improving the construction of instruments; but also, in an essential degree, by abandoning the use of a multitude of external applications, most of which were useless or hurtful.

But much improved as amputation has been, it cannot be dissembled that it is an operation at once terrible to bear, disagreeable to behold, and sometimes severe and fatal in its consequences, while the patient, if saved, is left for ever afterwards in a crippled mutilated state. Hence it is the surgeon's duty never to have recourse to so serious a proceeding, without a perfect and well grounded conviction of its necessity. Amputation should be generally regarded as the last expedient to which a surgeon ought to resort; an expedient justifiable, as a late writer says, only when the part is either already gangrenous, or the seat of so much injury, or disease, that the attempt to preserve it any longer would expose the patient's life to the greatest danger. (*Dict. des Sciences Méd.* t. i. p. 472.)

Although this amounts to a confession that the cure of some local disorders is not within the limits of our art, yet, on the other hand, it furnishes a proof that surgery may be the means of saving life, under circumstances which, without its assistance, would infallibly have a fatal termination. The operation is adopted as the safest measure: the cause is removed for the prevention of consequences. (*Graefe*, op. cit. p. 14.)

Nothing can be more absurd, or more misapplied, than the censures sometimes passed upon amputation, because the body is mutilated by it, &c. Although the objection proves the limitation of human knowledge and ability, it must be very unfair on this account to throw blame on surgery, or the practitioner who thus saves the patient's life. For, without dwelling upon the fact that a humane surgeon would never amputate through a mere love of operating, and without urgent cause,

one may simply ask, Are all diseases in their nature curable? Does not the surgeon cure such as are curable, without mutilation? And are not cases, which were in the beginning remediable, often first brought to the surgeon, when, from neglect, they have become totally incurable? Is it not his duty then to employ the only means left for saving the patient? And is not the preservation of a long and healthy life a compensation for the sacrifice? Indeed, is it not rather a greater honour to surgery, that, even when death has already taken possession, as it were, of a part, and is threatening inevitable destruction to the whole, a means is yet furnished, not only of saving the patient's life, but of bringing him into a state in which he may recover his former good health? (*Brünninghausen, Erfahrungen und Bemerkungen über die Amputation*, p. 11, 12mo. Bamberg, 1818.)

The first duty of the surgeon is, therefore, to ascertain with precision the cases which demand the operation, those in which it may be dispensed with, and the exact periods at which it should be practised. These are considerations requiring profound attention and the brightest talents. The most expert operator (as Mr. O'Halloran observes) may not always be the best surgeon. To do justice to the sick and ourselves, we must, in many cases, rather avoid than perform capital operations; and with respect to amputation, if we consider the many cases in which it has been unnecessarily undertaken, or done at unseasonable periods, it may be suspected that this operation, upon the whole, may have done more mischief than good. At all events, it is not enough for a surgeon to know *how* to operate; he must also know *when* to do it. (See *O'Halloran on Gangrene and Sphacelus: Preface*.)

For such reasons, I shall first take a view of some of the circumstances under which the best surgeons deem amputation necessary; though in each of the articles relative to the particular diseases and injuries which ever call for the operation, additional information will be offered. Some of these affect the bones or joints; others, more especially the soft parts. As a general maxim, it is the rule to amputate, whenever the injury, or disease, of the parts, is such, that either primarily, or consecutively, the limb must be lost, or symptoms induced putting the patient's life into imminent peril. (See *Dupuytren, Clin. Chir. t. iv. p. 234*.)

1. COMPOUND FRACTURES.

In a compound fracture, the necessity for amputation is not altogether proportioned to the seriousness of the accident, but frequently depends in part upon other circumstances. For example, in the field, and on board of a crowded ship, it is not constantly in the surgeon's power to pay such attention as the cases demand, nor to procure for the patient the proper degree of rest and good accommodation. In the field, there is often a necessity for transporting the wounded from one place to another. Under these circumstances, it is proper to have immediate recourse to amputation, in numerous cases of bad compound fractures, some of which, perhaps, might not absolutely demand the operation, were the patients so situated as to be capable of receiving all the advantages of the best and most scientific treatment in a well-ventilated, quiet house, or hospital, furnished with every desirable convenience.

At the same time, daily experience proves, that there are many other cases, in which it would be improper to have recourse to the knife, even under the most unfavourable circumstances of the above description. So, when a compound fracture occurs, in which the soft parts have not been considerably injured; in which the bones have been broken in such a direction that they can be easily set and kept in their proper position; or in which there is only one bone broken; amputation would be unnecessary and cruel. But, when the soft parts have been more extensively hurt, and the bones have been so badly broken, that perfect quietude and incessant care are required to afford any chance of recovery, it is a good general rule to amputate whenever these advantages cannot be obtained.

The bad air in crowded hospitals and large cities,—a circumstance so detrimental to wounds in general,—is another consideration which may seriously lessen the chances of saving a badly-broken limb, and should be remembered in weighing the reasons for and against amputation.

On this part of the subject, I find the sentiments of Graefe interesting. "Besides an absolute," says he, "there is a relative, necessity for amputation: it is the most mournful, and proceeds altogether from unfavourable external circumstances, though, alas! in many cases nearly unavoidable, when life is to be preserved. In war, every bloody action furnishes proof of what has been stated. The number of the wounded is immense; the number of surgeons for the duty too limited. The supplies most needed are at a distance. In those emergencies, though the military surgeon may, from routine and genius, be able to suggest the quickest method of obtaining what is wanted, know how to avail himself of every advantage which circumstances permit, and contrive tolerable substitutes for such things as are deficient, yet this will not always do.

"Who doubts (says Graefe) that a soldier with a gunshot wound, complicated with a smashed state of the bones, may sometimes be saved, without loss of his limb, by employing all the means which the resources of surgery offer? But these very resources are often wanting in a campaign: and the business of dressing the patient would occupy the surgeon several hours daily, during which his useful assistance could not be extended to other sufferers. Notwithstanding the utmost care, the removal of patients from one place to another frequently makes their wounds extremely dangerous, or fatal; and we now lose many a man, who, had he undergone amputation, would have been able to bear the journey." (See *Normen für die Ablösung grösserer Gliedmassen*, p. 15, 16.)

When a compound fracture is caused by the passage of a heavy body over a limb, such, for instance, as the broad wheel of a waggon or loaded cart, or by the fall of a very ponderous body on it, or by a cannon-shot, or by any other means so violent as to break the bones into many fragments, and so to tear, bruise, and wound the soft parts, that there shall be good reason to fear that there will not be vessels sufficient to carry on the circulation with the parts below the fracture, it becomes, as Mr. Pott observes, a matter of the most serious consideration, whether an attempt to save such a limb will not occasion loss of life. This

consideration must be given before any degree of inflammation has seized the part, and, therefore, immediately after the accident. When inflammation, tension, and a disposition to gangrene in the limb have arisen, the period is highly disadvantageous for operating, and the patient's chances of being saved by amputation, under these circumstances, are much smaller than before the changes here spoken of have taken place.

In compound fractures, as Mr. Pott has correctly pointed out, there are three points of time when amputation may be proper. The first of these is immediately, or as soon as possible, after the receipt of the injury. The second is, when the bones continue for a great length of time without any disposition to unite, and the discharge from the wound has been so long, and is so large, that the patient's strength fails, and general symptoms foreboding dissolution come on. The third is, when mortification has taken such complete possession of the soft parts of the inferior portion of the limb, quite down to the bone, that, upon the separation of such parts, the bone or bones are left bare in the interspace.

The first and second of these are matters of very serious consideration. The third hardly requires any.

The necessity of immediate or very early decision, in this case, makes it a delicate part of practice; for, however pressing the case may seem to the surgeon, it will not, in general, appear in the same light to the patient or his relations; yet suffering this point of time to pass often decides the patient's fate.

This necessity of early decision arises from the quick tendency to mortification, which ensues in the injured limb, and too often ends in the patient's death. That this is no exaggeration, says Pott, melancholy and frequent experience evinces, even in those whose constitutions, previous to the accident, were in good order; but much more in those, who have been heated by violent exercise, or labour, or liquor, or who have led debauched and intemperate lives, or who have habits naturally inflammable and irritable. This is often the case when the fracture happens to the middle part of the bones, but is much more likely to happen when any of the large joints are concerned. In many of these cases, a determination for or against amputation, is really a determination for or against the patient's existence.

That it would have been impossible to have saved some limbs, which have been cut off, no man will pretend to say; but this does not render the practice injudicious. Do not the majority of those who get into the above hazardous condition, and on whom amputation is not performed, perish in consequence of their wounds? Have not many lives been preserved by amputation, which, from the same circumstances, would otherwise most probably have been lost?

Pressing and urgent as the state of a compound fracture may be, at this first point of time, still it will be a matter of choice, whether the limb shall be removed or not; but, at the second period, the operation must be submitted to, or the patient must die.

The most unpromising appearances at first do not necessarily, or constantly, end unfortunately. Sometimes, after the most threatening first symptoms, after considerable length of time, great dis-

charges of matter, and large exfoliations of bone, success is ultimately obtained, and the patient recovers his health and the use of his limb.

Dupuytren relates two cases, in one of which the hand was terribly shattered by the kick of a horse; while, in the other, all the anterior part of the foot had been crushed by an iron machine. In the first case, all the parts of the hand, not broken to atoms, were preserved, the patient recovering without any severe symptoms. In the second, where the great toe was broken, and the first and second metatarsal bones comminuted, the other toes wounded, and all the integuments of the sole torn away, gangrene ensued; but, in the end, the patient recovered with the loss of only the great toe. In both these instances, Dupuytren removed all loose fragments of bone. In the last case, he was singularly favoured by the youth and good constitution of the patient. "Things," says he, "do not always end in this way: a very slight difference in these favourable conditions, or in the degree of the injuries, might perhaps have made us seriously repent of not having amputated." (*Clin. Chir. t. iv. p. 237.*)

But sometimes after the most judicious treatment through every stage of the disease; after the united efforts of physic and surgery; the sore, instead of granulating kindly, and contracting daily to a smaller size, shall remain as large as at first, with a tawny, spongy surface, discharging a large quantity of thin sanies, instead of a small one of good matter; the fractured ends of the bones, instead of tending to exfoliate, or to unite, will remain as perfectly loose and disunited as at first, while the patient shall lose his sleep, his appetite, and his strength; a hectic fever, with a quick, small, hard pulse, profuse sweats, and colliquative purging, contributing at the same time to bring him to the brink of the grave, notwithstanding every kind of assistance: in these circumstances, if amputation be not performed, Mr. Pott asks, what else can rescue the patient from destruction?

The third and last period is a matter which does not require much consideration. Too often, the inflammation, consequent upon the injury, instead of producing abscess and suppuration, tends to gangrene and mortification, the progress of which is often so rapid as to destroy the patient in a short space of time, constituting that very sort of case in which amputation should have been immediately performed. But sometimes even this dreadful malady is, by the help of art, put a stop to, but not until it has totally destroyed all the surrounding muscles, tendons, and membranes quite down to the bone, which, upon the separation of the mortified parts, is left quite bare, and all circulation between the parts above and those below is by this totally cut off. In this instance, whether the surgeon saw through the bare bone, or leave the separation to be effected by nature, the patient must lose his limb. (See *Pott's Remarks on the Necessity of Amputation in certain Cases, &c. Chir. Works, vol. iii.*)

At the same time, there are certain examples of mortification from external causes, where, as far as one can judge from the results of later experience than that of Mr. Pott, the surgeon should not defer amputation, even though the disorder is yet in a spreading state, attended with considerable swelling and tension reaching far up the limb. This is a subject, however, which will re-

quire more explanation hereafter. (See what is presently said on *Mortification*.) Nor are the cases, to which reference is made, meant to affect the general truth of the observation, delivered by the most experienced surgeons of every age, that, when a limb is extensively swelled and inflamed, with a part of it either in a state of spreading mortification, or ready to become gangrenous, the period is so unfavourable for amputation, that very few patients, so circumstanced, ever recover after the operation. Nor is it meant to be insinuated, that, in the very cases, which form exceptions to the general rule of not amputating before the tendency to gangrene has ceased, the patient might not have had an infinitely better chance of his life, had the operation been done immediately after the first receipt of the injury, before any disposition to gangrene had had time to be produced.

[The period at which amputation may most advantageously be performed has been a subject of discussion among surgeons for a period of nearly a century, the majority being in favour of immediate or primary amputation, (agreeing, therefore, in the doctrines of Mr. Pott, which have been just quoted,) while others, among whom may be mentioned Hunter and Abernethy, have advocated delay. M. Boucher, in a memoir addressed to the French Academy, defined *three* periods for operation, 1. The period between the receipt of the injury and the appearance of the inflammatory symptoms. 2. When the inflammatory action has commenced, and is more or less capable of disturbing the animal economy. 3. When the violence of the inflammatory symptoms and symptomatic fever have abated; that is, when the suppurative stage is fully established. This division of periods has been sanctioned and adopted by Mr. Guthrie, and also by Mr. Rutherford Alcock. The first and *third*, it will be seen, correspond to the first and *second* of Mr. Pott, the second is a further subdivision and is intermediate between the other two.

Mr. Alcock considers this further distinction an important one, and he proposes the terms *primary*, *intermediary*, and *secondary*, to designate the operations performed at the three several periods. He considers that the intermediary "differ greatly from the others in the principal circumstances which are held to influence the propriety of the amputation and its result, and ought neither to be classed with the primary of the first class, or the secondary of the third." (*Medical Hist. of the Spanish Legion*, 1838, p. 66.) This intermediary period is unquestionably the most unfavourable of the three, and Sir G. Ballingall observes, that "as it is a period which no one advocates or adopts from choice, a period, in short, in which amputations are looked upon as compulsory and undertaken with reluctance, their number is not likely to be great, and the main question comes again to lie between primary and secondary operations." (*Military Surg.* ed. 5, 1855, p. 424.)

It is desirable, however, that these intermediate cases should be distinguished from the other two classes, in estimating results, or they will lead to erroneous deductions. Looking upon them as compulsory operations, they should be excluded altogether from the calculation, in estimating the comparative merits of the primary and secondary periods, properly so called.

It is from the experience of military surgeons

that the principal deductions in favour of primary amputations, as compared with secondary, have been drawn. There is, however, a considerable difference between military and civil surgery in this respect, the contrast between the results of primary and secondary amputations being by no means so well marked in the latter as in the former. According to Mr. Alcock, "The same proportion no longer exists, nay, is not seldom reversed:" and Sir G. Ballingall says, "Upon this point I have had as good opportunity of forming an opinion as most of my contemporaries, having now served thirteen years in the former, and nearly thirty in the latter. In civil hospitals the comparative success of primary amputation has been by no means so great as that which I was accustomed to see and to hear of in the army. Sanson, who has noticed this fact, has assigned several reasons obviously leading to a different result; and amongst these, the moral influence of the different circumstances under which a patient is received into a civil and into a military hospital, has always appeared to me one of the most important. A tradesman, with perhaps an indifferent constitution, and a wife and family dependent on his exertions, is admitted with an injury requiring amputation, which may be the result of an accident originating in intoxication, ignorance, or folly, and by which he finds himself suddenly reduced to misery and dependence: while the soldier, again, with a constitution originally sound, and accustomed to contemplate such an accident, loses his limb in a good cause, under circumstances creditable to himself and duly appreciated by his country, from which he is certain of a pension for life." "In addition to the powerful effect which this moral contrast must necessarily produce, there is a physical cause operating, which I believe to be one of the most influential, although one of the least observed. A soldier going from a filthy billet or a crowded barrack room, into a clean well aired, and well regulated, military hospital, goes often from a worse atmosphere into a better, while a mason or house carpenter accustomed to work all day in the open air, is taken into a large civil hospital constantly occupied with its full complement of patients, and having its atmosphere thereby necessarily vitiated." (*Mil. Surg.* p. 423, ed. 5, 1855.)

Mr. Alcock is likewise in favour of primary amputation, although he does not recommend it quite so exclusively as other military surgeons. In fact, he found, in his own experience while attached to the Spanish Legion, that his primary were not so successful as his secondary operations; and he thinks, therefore, that the latter have been too indiscriminately condemned. For a full discussion of the whole subject, the reader is referred to Mr. Alcock's valuable and elaborate lectures on Amputation (see *Lancet*, 1840-41); but the following are his principal deductions on the present question. He thinks errors have been introduced into both sides of the argument, and that "*the mortality of the secondary has been greatly exaggerated, and the dangers of the primary underrated*," but that, on the other hand, the advocates for secondary operations have equally lost sight of all the lives lost with and without operation, in the intervening period between the first and twentieth day." (*Lancet*, vol. ii. 1840-41, p. 292.) Mr. Alcock holds that "primary

amputation is, beyond question, the best practice in the majority of instances, *not because the human system is at that period in the best state for meeting the consequences of the double shock, moral or physical* — not because these present such decidedly more favourable results than secondary amputations, under every condition of circumstances (when the latter are not compulsorily performed), but because *many will be the forced amputations in an intermediate and still less favourable period ; many more the deaths before the favourable period arrives ; and a large number even then remain who arrive at that period, but offer no reasonable chance of surviving the shock of an operation if superadded on the diseased and exhausting actions to which the original injury had given rise.* Add all these deaths to those from secondary amputation (properly so called) and he must be a bigot indeed to the adverse opinion, who can have one moment's hesitation as to which side of the question the amount of human suffering and the loss of human life preponderates" (loc. cit. p. 292). M. Velpeau says, "The fundamental argument of the partizans of temporization, to wit, that a multitude of mutilated persons would have been enabled to save their limbs, if the surgeon had delayed, is more specious than solid ; for we can reply to them, that a goodly number of the other cases would be *living with three limbs*, if, in delaying the operation they had not *suffered them to die with four.*" (*Elem. of Op. Surg.* vol. ii. p. 469. Mott's Translation.) The opinions of Mr. Alcock, as quoted above, embody, we believe, as nearly as possible, the doctrine of the great majority of surgeons of the present day, and that doctrine may be briefly stated as follows : when the injury is such that it is obvious that there is no chance for the ultimate preservation of the limb, primary amputation should always be preferred ; but when the surgeon has doubts on this point, which will very frequently be the case, for the question is often one of the greatest possible difficulty and delicacy, he should give the limb the benefit of the doubt, holding the alternative of secondary amputation in reserve in case of need ; the results of this latter, if not equal to those of the former, being yet sufficiently favourable, in civil practice especially, to warrant the delay.

Primary amputation, however, is not always to be "*immediate*" in the literal sense of the word, but the state of collapse, or shock, which is often the immediate effect of a serious injury, must be allowed to pass off before the operation is attempted. The surgeon may often wait with advantage, as Mr. Guthrie recommends (see article GUNSHOT WOUNDS), for six or eight hours or even longer, cordials being administered at intervals until reaction has duly taken place. A still longer delay is in many cases admissible, although Mr. Skey perhaps goes too far in thinking that "the condition of the patient is as favourable for amputation at the expiration of thirty-six, or even forty-eight hours, as at the expiration of three or four."

On the question of reaction after serious accidents, the last named author thinks sufficient distinction is not made "between the consequences of violence done to the circulating and that to the nervous system. A man receives a severe blow on the abdomen or elsewhere ; his nervous system sustains the first effect of the shock ; his pulse sinks till it becomes almost imperceptible, but he has lost no blood. To amputate a limb which may have been

fractured, or crushed, or otherwise severely or hopelessly mutilated, in this condition of his system, is to hurry him on to his death. The cause is a shock which time can, and under favourable circumstances will, remedy. We give him stimulants, and his circulation rallies ; his physical powers revive, and in the course of one or more hours, we amputate, with success. Contrast this case with that of a man reduced to an equal degree of prostration by *loss of blood*, consequent on severe compound fracture or mutilation of any kind. In such a case how can we expect reaction to take place with the circulation reduced by a large diminution from its standard quantity." Mr. Skey thinks that in the former case we should postpone the operation until reaction has taken place, but in the latter (that is, if there exist good grounds for believing the hemorrhage to have been considerable) we must attribute the prostration primarily to that cause, and resort to immediate amputation. (*Skey, Op. Surg.* p. 315.)]

For the consideration of a variety of complicated circumstances affecting the question of amputation in compound fracture, I must refer to GUNSHOT WOUNDS.

2. EXTENSIVE CONTUSED AND LACERATED WOUNDS.

These form the second class of general cases requiring amputation. Wounds without fracture are not often so bad as to require this operation. When a limb, however, is extensively contused and lacerated, and its principal blood-vessels are injured, so that there is no hope of a continuance of the circulation, the immediate removal of the member should be recommended, whether the bones be injured or not. Also, since no effort on the part of the surgeon can preserve a limb so injured, and such wounds are more likely to mortify than any others, the sooner the operation is undertaken the better.

In these cases, as in those of compound fractures, though amputation may not always be necessary at first, it often becomes so afterwards. The foregoing observations, relative to the second period of compound fractures, are equally applicable to badly lacerated wounds, unattended with injury of the bones. Sometimes a rapid mortification comes on ; or a profuse suppuration, which the system can no longer endure.

For information on the proper period of amputating in traumatic gangrene, see MORTIFICATION, and the section on this disorder in the present article.

3. CASES IN WHICH PART OF A LIMB HAS BEEN CARRIED AWAY BY A CANNON-BALL.

When part of a limb has been torn off by a cannon-ball, or any other cause capable of producing a similar effect, the formation of a good and serviceable stump ; the greater facility of healing the clean, regular wound of amputation ; and the benefit of a far more expeditious, as well as of a sounder cure, are the principal reasons which here make the operation advisable.

This was an instance, in which some former surgeons disputed the necessity of amputation. They urged as a reason for their opinion, that the limb being already removed, it is better to endeavour to cure the wound as speedily as possible than increase the patient's sufferings and danger,

by making him to submit to amputation. It must be remembered, however, that the bones are generally shattered, and reduced into numerous fragments; the muscles and tendons are unequally divided, and their ends torn and contused. Now, none of the old surgeons questioned the absolute necessity of extracting the splinters of bone, and cutting away the irregular extremities of the tendons and muscles, which operations would require a longer time than amputation itself. Besides, we should recollect that, by making the incision above the injured part, so as to be enabled to cover the bone with flesh and integuments perfectly free from injury, the extent of the wound is so diminished, that the healing can be accomplished in one third of the time which would otherwise be requisite, and a much firmer cicatrix is also obtained. Such reflections must convince us that amputation here holds forth great advantages. It cannot increase the patient's danger; and as for the momentary augmentation of pain which he suffers, he is amply compensated. (See GUNSHOT WOUNDS.)

4. MORTIFICATION.

Mortification is another cause, which, when advanced to a certain degree, renders amputation indispensably proper. We have noticed, that bad compound fractures, and wounds, often terminate in the death of the injured limb. In such cases, there can be no doubt that the operation is generally the safest and most advantageous measure. Nay, there are, as we shall presently see, certain forms of mortification, in which the early performance of amputation is the only chance of saving the patient.

Practitioners have entertained very opposite opinions concerning the period when one should operate in cases of mortification. Some pretend that whenever the disorder presents itself, and especially when it is the effect of external violence, we should amputate immediately the mortification has decidedly begun to form, and while the mischief is in a spreading state. Others believe that the operation should never be undertaken before the progress of the disorder has stopped, even not till the dead parts have begun to separate from the living ones.

The advocates for the speedy performance of amputation declare, that the further progress of the mortification may be stopped, and the life of the patient preserved, by cutting above the parts affected. However, according to the reports of the greater number of eminent surgical writers, this practice is highly dangerous, and undeserving of confidence. Whatever pains may be taken, in the operation, only to divide sound parts, there is no certainty of succeeding in this object, and the most skilful practitioner may be deceived. The skin may appear to be perfectly sound and free from inflammation, while the muscles which it covers, and the parts immediately surrounding the bone, may actually be in a gangrenous state. But even when the soft parts are found free from apparent distemper on making the incision, still, if the operator should not have waited till the mortification has ceased to spread, the stump will almost always be attacked by gangrene. Surgeons who have had opportunities of frequently seeing wounds which have a tendency to mortify, entertain the latter opinion. Such was the sentiment of

Pott, who says that he has often seen the experiment made, of amputating a limb in which gangrene had begun to show itself, but never saw it succeed, and it invariably hastened the patient's death.

The operation may be postponed, however, too long. Mr. S. Sharp, in particular, recommended too much delay, advising the operation never to be undertaken till the natural separation of the mortified parts had considerably advanced. Mr. Sharp was a surgeon of immense experience, and his authority carries with it the greatest weight. But, perhaps, he was too zealous in his opposition to a practice, the peril of which he had so often beheld. When the mortification has ceased to spread, there is no occasion for further delay. We now obtain, just as certainly, all the benefits of the operation, and get rid of a mass of putridity, the exhalations from which poison the atmosphere which the patient breathes, and are highly detrimental to his health. Nay, patients in these circumstances may actually fall victims to the absorption of putrid matter. However, this danger would not be so considerable as that which would arise from too precipitate an operation; and it is better to defer amputation a little more than is absolutely requisite, than run any risk of performing the operation before it is certain that the parts have lost their tendency to gangrene.

In the article MORTIFICATION, we have noticed particular cases of gangrene, where, the surgeon is not to wait for the line of separation being formed, but have recourse to the immediate performance of amputation. The experience of Mr. Lawrence, and several cases which I saw in the British military hospitals during the last war, tend to confirm the propriety of such practice. (See *Medico-Chir. Trans.* vol. vi. p. 156, &c.)

In an example, where a large part of the arm was deeply affected with gangrene from external violence, and the disorder was yet making rapid progress, I once recommended the performance of amputation at the shoulder-joint. On the whole, this instance was favourable to the practice; for, though the patient died at the end of a fortnight, probably he would not have lived twenty-four hours, had the operation not been done; nor was the stump attacked with mortification,—a circumstance worthy of attention, because it is a danger particularly insisted upon by the opponents of amputation under the preceding circumstances; and, had it not been for a large abscess, which formed in the back, as was supposed, from a violent blow received in the fall which produced the original injury, there were well-grounded hopes of recovery.

There is likewise a species of gangrene, which is pointed out by Mr. Guthrie, as requiring early amputation. "A soldier (says he) shall receive a flesh-wound from a musket-ball in the middle of the thigh, which passes through the limb apparently, on a superficial inspection, without injuring the main artery; or it shall pass close behind the femur, where the artery turns to the back part of the bone; or it may go through the middle of the bone, from behind forwards, between the condyles of the femur, into the knee-joint, and the patient shall walk to the surgeon with little assistance, be superficially dressed, and, in many cases, considered slightly wounded; yet the femoral artery and vein, in the whole of these cases,

and, indeed, in many others, shall be wounded, or cut across, and the local inflammation be so slight as to obtain little attention. On the third or fourth day, the patient shows his toes discoloured, and complains of pain and coldness in the limb below the wound, the constitution begins to sympathise with the injury, and the surgeon probably thinks the case extraordinary. Perhaps he suspects the real state of the injury; but is surprised that a wound of the femoral or popliteal artery, with so little attendant injury, could cause mortification, &c. He is anxious to do something; but mortification, or at least gangrene, having commenced, he must, according to general rule, await the formation of the line of separation. The temperature of the leg, a little above the gangrene, is good, perhaps higher than natural; he hopes it will not extend farther, and it probably does remain stationary for a little time. At last, the parts originally affected—the toes—become sphacelated, and gangrene quickly spreads up the leg as far as the wounded artery, by which time the patient dies."

For the purpose of preventing such a disaster, where the artery, or artery and vein, have been divided, Mr. Guthrie recommends the performance of amputation as soon as the gangrene is perceived to extend beyond the toes: and the swelling and slight attendant inflammation, which is marked more by the tumefaction than the redness of the part, has passed higher up than the ankle. (See *Guthrie on Gunshot Wounds*, p. 60, 61.)

Mortification of a limb, after operation for aneurism, is another exception to the general rule of not amputating till the mortification has stopped. Where also gangrene arises from the obstruction of the circulation, by an aneurism bursting, and its blood passing copiously into the cellular tissue of the limb, amputation should be performed without delay, though the mortification may not have stopped. An example of the success of this practice, I have laid before the profession. (See *Med. Chir. Trans.* vol. xvi.)

5. DISEASED JOINTS.

Excluding from present consideration the proposal to undertake the excision of some joints which are in particular states of injury, or disease, I may observe, that scrofulous joints, with diseased bones, and distempered ligaments and cartilages, is another case in which amputation may become absolutely necessary. As Mr. Pott remarks, there is one circumstance attending this complaint, often rendering it particularly unpleasant, which is, that the subjects are most frequently young children, so as to be incapable of determining for themselves: which inflicts a distressing task on their nearest relations. All the efforts of physic and surgery often prove absolutely ineffectual, not only to cure, but even to retard the disease in question. Notwithstanding many cases admit of cure, numerous others do not. The disease often begins in the very inmost recesses of the cellular texture of the heads of the bones forming the large articulations, such as the hip, knee, ankle, and elbow; the bones become diseased in a manner which will be explained in the article JOINTS, sometimes with great pain and symptomatic fever; sometimes with little of either, at least in the beginning. The cartilages covering the ends of these bones, and designed for the mobility of these joints, are totally destroyed;

the epiphyses in young subjects are either partially, or totally separated from the said bones; the ligaments of the joints are so thickened and spoiled by the distemper, as to lose all natural appearance, and become quite unfit for all the purposes for which they were intended: the parts appointed for the secretion of the synovia, become distempered in like manner. All these together furnish a large quantity of stinking sanious matter, which is discharged either through artificial openings, made for the purpose, or through small ulcerated ones. These openings commonly lead to bones which are diseased through their whole texture. When the disease has got into this state, the constant pain, irritation, and discharge bring on hectic symptoms of the most destructive kind, such as total loss of appetite, rest, and strength, profuse night sweats, and as profuse purgings, which foil all the efforts of medicine, and bring the patient to the brink of destruction. (See *Pott on Amputation*.)

In these cases, amputation is attended with more success when performed late, than when undertaken at an early period, before the disease has made great advances. This is fortunate, as it affords time for a fair trial of such remedies as are best calculated to check the progress of the disorder. (See JOINTS.)

Whenever the disease of a joint is likely to terminate in ankylosis, amputation should not be resorted to, as a cure will be effected without it (See ANCHYLOSIS.) In deciding to amputate, or not, a great deal will depend upon the state of the patient's health, and his kind of constitution, as well as upon the condition of the joint itself.

[The treatment of diseased joints by excision of the articular extremities of the bones, has of late years been adopted with signal success in many cases in which formerly the entire limb would have been sacrificed, and the number of amputations performed for this class of diseases has in consequence materially diminished. Nevertheless, there will always remain cases to which excision is inapplicable, and in which amputation may become absolutely necessary. When the disease commences in the bones, and when these are affected for some distance from the articulation, so as to render it impossible to *excise* the whole disease without removing *more* than the articular extremities of the bones; when, also, the soft parts are extensively disorganised, and there are abscesses and sinuses extending upwards and downwards along the limb; when it is not probable that the patient will have sufficient strength to support him through the protracted effort of repair that excision will demand from him; or when the constitutional symptoms are such as to render it necessary to remove speedily and completely the source of irritation by which his life is endangered, in all such cases, amputation is the alternative which must still be resorted to, and the injudicious employment of excision would only serve to bring undeserved discredit on one of the most valuable improvements which have been introduced into modern surgery.]

6. NECROSIS.

Another distemper, sometimes producing a necessity for amputation, is necrosis, or the death of the whole, or of a considerable part, of the bones of the extremities, accompanied with such extensive abscesses, such disease of the soft parts, such

disorder of the constitution, and prostration of strength, that every hope of a cure being effected by a natural process must be renounced. By necrosis, is here meant, not merely some disease which destroys the surface of a bone, but one which extends its depredations to the whole of the internal substance, and that from end to end. Portions of the bones die from a variety of causes, such as struma, lues venerea, deep-seated abscesses, pressure, &c.; and bones in this state, when properly treated, often exfoliate and cast off their dead parts. But, when the whole substance of a bone becomes diseased, from end to end, frequently no means will avail. Nevertheless, I would not positively affirm, as Mr. Pott has done, that every extensive necrosis, affecting a bone nearly its whole length, must inevitably require amputation. The power of nature in restoring the bones is sometimes wonderful. (See NECROSIS.)

When, however, in a case of necrosis, the limb breaks in the midst of the diseased part of it, followed by vast deformity, profuse suppuration, and urgent constitutional derangement, amputation is indicated. (See *Dupuytren, Clin. Chir.* t. iv. p. 260.)

7. CANCEROUS AND OTHER INVETERATE DISEASES.

Cancerous diseases, and malignant incurable ulcers on the limbs, sometimes render amputation a matter of necessity. In treating of cancer, we shall remark, that little or no confidence can be placed either in internal or any kind of topical remedies, and that there is nothing except the total separation of the part affected, upon which any rational hopes of cure can be built. Cancer, of the scirrhus variety, is not frequently seen on the extremities. Every man of experience, however, must occasionally have seen, in this situation, if not *scirrhus*, as it is termed by Dr. Carswell (see his *Illustrations of the Elementary Forms of Disease*, Fasc. 1 et 2), medullary tumors, and other diseases quite as intractable, and which cannot be cured, except by removing the affected part. This may often be accomplished without cutting off the whole limb: but when the disease has spread beyond certain bounds, amputation, above the part affected, is the only thing to which recourse can be had with any hope of success. In a few cases of medullary tumor, the operation has succeeded; and even after the disease had reappeared, a cure has now and then been achieved by another excision of the diseased parts. Yet, from what I have seen of fungus hæmatodes, I should much doubt, whether the benefit obtained by amputation would frequently be lasting, as when this disease shows itself only externally, internal organs are mostly at the same time similarly affected. (See FUNGUS HÆMATODES.)

Besides cancerous, there are other ulcers, which may render amputation indispensable. Thus, when an extensive ulcer, of any sort whatsoever, is evidently impairing the health; when, instead of yielding to remedies, it becomes larger and more inveterate; when, in short, it puts life in imminent danger; amputation should be advised.

8. VARIOUS TUMORS.

Tumors commencing in the soft parts, if we except those of malignant nature, may generally

be removed without sacrificing the limb; but it is otherwise with those which originate in the osseous tissue, as the enchondromatous and other tumors of bone. Occasionally, perhaps, when the tumor grows from the surface of a bone and has not a very extended basis of attachment, excision of the tumor only may be successfully practised, but in the majority of cases, the whole thickness of the bone is implicated to a greater or less extent, and in these, since their dispersion is out of the question, amputation of the limb is the only resource.

Exostosis may render amputation necessary, when the tumor becomes hurtful to the health, or insupportable, on account of its weight, or other circumstances, and cannot be removed by any of the plans specified in the article EXOSTOSIS.

Before the late facts and improvements relative to the treatment of aneurisms on the extremities, these cases were generally set down as requiring amputation. Even Pott, and J. L. Petit, wrote in recommendation of such practice, and their observations on this subject are among the few parts of their writings which the enlargement of surgical knowledge, since their time, has rendered objectionable. The surgeon, to whom the honour of first correcting this erroneous doctrine belongs, is A. N. Guenault, who opposed the advice delivered by Petit. (*Haller, Disp. Chir.* vol. v. p. 155.)

I shall conclude these remarks on the cases requiring amputation, with advising surgeons never to undertake this serious operation without consulting the opinions of other professional men, whenever their advice can be obtained. The best operators are often deficient in that invaluable kind of judgment, by which the cases, absolutely demanding amputation, are discriminated from others, in which the operation may be wisely postponed, and a chance taken of preserving the limb.

Surgeons should generally refuse to amputate limbs merely affected with stiffness or deformity. Operations under such circumstances, termed by the French *opérations de complaisance*, are more frequently followed by fatal consequences than amputations in more urgent cases. (See *Dupuytren, Clin. Chir.* t. iv. p. 271.)

THE HISTORY OF AMPUTATION

Evinces, that the steps of surgery to perfection are slow, and that they even sometimes deviate from the straight path, though, upon all essential points, no retrogradation has ever taken place. Here nature has acted as the guide, and the surgeon's chief merit has consisted in obeying the hints which she herself has thrown out. As already mentioned, the following natural occurrence, no doubt, was one of the circumstances which first led to the bold practice of amputation; in consequence of disease, and grievous local injuries, whole limbs were sometimes seized with mortification. In the majority of cases this was attended with so much constitutional disturbance, that the patients died; but, in other instances, the mortification was confined to the part; suppuration was established between the dead and living parts; the whole of the mortified limbs fell off; the suppurating surfaces healed up; and thus, by the powers of nature, the patients were restored to health. Here was clearly proved the possibility of recovery, notwithstanding the loss of a limb. The surgeon, as Brünninghausen remarks, viewed with surprise this course of nature, and hardly ventured to pro-

mote it by the feeble means formerly employed. But, as the mortified parts, previously to their detachment, caused great annoyance by their fetor, a surgical attempt was at length made to get rid of them; in doing which, the knife was always kept from touching the living flesh, on account of a well-grounded fear of bleeding, for the suppression of which no effectual methods were known. Such was the practice that prevailed from Hippocrates down to Celsus. (*Erfahr. &c. über die Amp.* p. 14.)

A. C. Celsus, who lived in the reign of Tiberius, and whose book, *De Re Medicâ*, should be read by every surgeon, has left us a short description of the mode of amputating gangrenous limbs. (Lib. vii. c. 33.) It has been often remarked, that Celsus has left no instructions for securing the divided blood-vessels; but it has not been commonly noticed, that, in his chapter on wounds, he directs us to stop hemorrhage by taking hold of the vessels, then tying them in two places, and dividing the intermediate portion. If this measure cannot be adopted, he advises the use of a cauterizing iron. Several hints are to be met with in the writings of Celsus, from which it may be inferred, that the ligature of bleeding vessels was sometimes practised at the early age in which he lived; and this supposition is strengthened, by a fragment of Archigenes, preserved by Cocchius, on the subject of amputation, where he speaks of tying, or sewing, the blood-vessels. We are not, however, in possession of all the writings of medical authors, prior to the time of Galen, and must therefore remain in doubt upon this point. (*Rees's Cyclopædia*, art. *Amputation*.)

It has been argued, therefore, with some appearance of reason, that if amputation often proved fatal in the days of Celsus,—“*sæpe in ipso opere*,” as the expression is,—it was owing to the want of some efficacious method of compressing the blood-vessels during the operation itself.

But, admitting that the ancients were not altogether uninformed of the plan of tying arteries, it cannot be credited that they adopted the practice to any extent; for, if they had, they would not have continued so partial to the cautery, boiling oils, and a farrago of astringent applications. They would also never have had recourse to the barbarous method of cutting the flesh with a red-hot knife, with the view of stopping the hemorrhage by converting the whole surface of the stump into an eschar. Painful in its execution, and horrid in its consequence, as this burning operation was, it seldom proved a lasting antidote to the bleeding, which generally came on in a fatal manner, as soon as the sloughs were loose. On this part of the subject my own ideas fully agree with those of a distinguished foreign surgeon, who says, that although the document left us may prove that the ligature was known to the ancients, and employed in cases of aneurisms and wounded blood-vessels, nay, that the arteries were secured with a needle and ligature; yet the practice could not have been extended to the operation of amputation, since, with the custom of making the incisions in the dead parts, the method scarcely admitted of being put in execution. (*Brünninghausen, Erfahr. über die Amput.* p. 29.)

At the period of making the incision, the ancients contented themselves with having the skin forcibly drawn upward by an assistant; they next

divided, with one sweep of the knife, the integuments and flesh down to the bone, and, afterwards, sawed the bone on a level with the soft parts which were drawn upward. Celsus considered it better to let the incision encroach upon the living flesh, than leave any of the diseased parts behind. “*Ei potius ex sanâ parte aliquid excidatur, quam ex ægrâ relinquatur.*” (*De Medicinâ*, lib. vii. c. 33.)

It appears, however, that his views extended further than those of most of his contemporaries, and even his followers, almost down to modern times. After cutting the muscle down to the bone, he says, that *the flesh should be reflected, and detached underneath with a scalpel, in order to denude a portion of the bone which is then to be sawn as near as possible to the healthy flesh, which remains adherent.* He states that, when this plan is pursued, *the skin around the wound will be so loose, that it can almost be made to cover the extremity of the bone.* It is to be lamented, that this advice inculcated by Celsus, should not have been comprehended or that it should have been so neglected as to stand in need, as it were, of a new discoverer. But, the fact is, that hemorrhage formerly rendered amputation so dangerous that the ancient surgeons could not devote much attention to anything else in the operation, and practitioners amputated so seldom, that we read in Albucasis, that he positively refused to cut off a person's hand, lest a fatal hemorrhage should ensue, and the patient did it himself and recovered. Over that part of the stump which the small quantity of preserved skin would not cover, Celsus recommended compresses, and a sponge dipped in vinegar to be laid. (*De Re Medicâ*, lib. vii. c. 33.)

Archigenes, born at Apamia in Syria, was the disciple of Agathinus, and physician to Philip, king of that country. He repaired to Rome, where he practised physic and surgery in the reign of the emperor Trajan, about 108 years after the birth of Christ. (*Portal. Hist. de l'Anatomie et de la Chirurgie*, t. i. p. 61.) In the history of amputation, the name of Archigenes is conspicuous; for he is supposed to have been the first to apply a circular ligature to the limb: he also wetted the whole member with cold water, for the prevention of loss of blood; and it is sometimes believed that he entertained some notion of previously taking up the vessels. Dupuytren observes, however, that this is very doubtful, because it would imply such anatomical knowledge of the circulation as did not exist at the early period alluded to. Archigenes imitated Celsus in the important point of making the incisions in the sound flesh. (*Nicet. Coll. Chir.* p. 155; *Sprengel, Geschichte de Chir.* b. i. p. 404. Halle, 1805.) Such was likewise the practice of Heliodorus, who at this early period made objections to the plan of cutting off a limb by a single stroke—a proposal that was renewed in far later days. The same author has also spoken of amputating at the joints; a method of which he disapproves. (*Nicet. Coll. Chir.* p. 155.) However, Galen entertained a favourable opinion of it. (*Com. 4*, in lib. *de Artic.* p. 650.) Galen's precepts concerning amputation are, upon the whole, very like those of Hippocrates; for he directs only the dead parts to be cut, and the stump to be cauterized. (*De Arte Curativâ ad Glauconem*, lib. ii.) By all the old writers, amputation was

entirely restricted to cases of mortification ; further they were afraid to go ; and this precept, and all the other doctrines of Galen, may be said to have been the guide of the whole surgical profession for at least fourteen centuries.

The timid Arabians were not partial to amputation ; and even in cases of mortification, generally preferred a farrago of useless applications, like Armenian bole, &c. Paulus Ægineta, like Galen, deviated from Celsus's good rule of making the incisions in the healthy parts, and only approved of making the requisite division near them. (Lib. iv. c. 19, p. 140.) Avicenna repeated the directions left by the Greek writers (*Can. lib. iv. Fen. 3, tr. 1, p. 454*), and Albucasis recommended the performance of the operation with a red-hot knife. (*Chirurg. lib. i. sect. 52, p. 99.*) In the middle ages, little was done for the improvement of amputation. But in the fourteenth century, gunpowder was invented, and soon applied to the purposes of war ; so that an abundance of cases must have presented themselves, in which the wise maxim of not deferring amputation until mortification had come on, but of preventing the mischief by the operation, ought to have struck an intelligent surgeon. One might also have expected that practitioners would now have been led to make the incisions in the sound flesh. Unfortunately, the invention of gunpowder, and its immediate consequences in surgery happened at a period when practitioners were ill qualified to profit by the new lessons of experience set before them. The writings of their predecessors furnished them with no directions how they ought to act, and they were themselves too much confounded at the sight of the mischief for which they were consulted, to be able to form any correct opinion about causes and effects. Their first idea was, that the terrible symptoms proceeded from the parts being actually burned, and they afterwards inclined to believe that gunshot wounds were poisoned. Hence the most absurd modes of treatment were instituted, and, as Brünninghausen expresses himself, human nature groaned under a new evil, for which there were for some time no judicious plans of relief. (*Erfahr &c. über die Amp. c. 19.*) This deplorable state was the natural result of the depression of science in general, and of the healing art in particular, in the days to which I now refer. In these middle ages, as they are called, the population of all Europe was plunged in the deepest ignorance ; and whatever little knowledge remained either of the arts, or languages, was monopolized by the priesthood, the physicians of those times, who instead of studying the volume of nature, wasted most of their time in discussing the doctrines of Galen. Surgery itself sunk to the lowest ebb, as may be well conceived from the decrees issued by Pope Boniface the Eighth, forbidding any of the clergy to do any thing themselves which drew blood ; and of course, all the operative part of surgery was transferred to a set of illiterate, low-bred mechanics, far inferior to the worst country farriers of modern times. Yet, the clergy, who were thus scrupulously averse to soiling their own hands with blood, or hurting their own tender feelings by viewing the agony of their fellow-creatures, when submitted to operations, had no hesitation in taking the chief emoluments and honours of the profession, or in turning over these poor sufferers to men more qualified to torture and murder than give relief ; and,

what nearly staggers all credulity, the same professors of Christianity, who shuddered to spill a drop of blood themselves on a proper occasion, as Haller observes, eagerly had a hand, and acted an important part in every sanguinary war where it was possible for them to interfere. In these dismal days of surgery, the advice delivered by Celsus was renewed by Theodoricus, who used to administer opium and hemlock previously to the operation, for the purpose of rendering the patient less sensible of pain, and afterwards vinegar and fennel were given, with the view of dispersing the intoxicating effects of the preceding medicines. (*Chirurg. lib. iii. c. 10.*)

The renowned Guido di Caulico was the inventor of the plan of taking off limbs without bloodshed. It is better, says he, for the limb to drop off, than be cut off. This practice consisted in covering the whole member with pitch plaster, and applying round one of the joints so tight a band that the parts below the constriction ultimately dropped off. (*Chirurg. tr. 6, Doctr. 1, cap. 8.*) The method of amputating, suggested by Celsus, was again revived by Gersdorf, who, after the operation, not only drew down over the stump the skin which had been retracted, but applied a hog's or bullock's bladder over the stump, so as to render all burning and stitching of the part needless. (*Feldbuch der Wundarzn. fol. 63.*) Bartholomew Maggi also endeavoured to preserve a considerable flap of integuments for covering the stump. (*De Vulner. Bombard. et Sclopet. 4to. Bonon. 1552 ; see Sprengel's Geschichte der Chirurgie, p. 404, 406, 8vo. Halle, 1805.*)

At length, in the 15th century, when the revival of learning had commenced in Italy, medical practitioners began to think for themselves again, and they turned from compilations and scholastic nonsense to the consideration of nature. Anatomy was cultivated with great ardour, and made brilliant progress under eminent characters of the time ; De la Torre, Berengarius Carpi, Vesalius, Fallopius, Eustachius, and others, who were also for the most part very distinguished surgeons. "*In Italiâ scientiarum matre medici se nunquam chirurgia abdicarunt. Seculo 15 et 16, professores medici academîæ Bononiensis, Patavinæ, et aliarum in Italia illustrium scholarum et manu curaverunt, et consilio, et inter istos viros summi chirurgi extiterunt.*" (*Haller, Bibl. Chir. b. i. p. 161.*) Practitioners now ventured to amputate limbs in the sound part for other incurable diseases besides mortification ; but the art of stopping hemorrhage after the operation continued imperfect. Though the method of applying the ligature in cases of wounded arteries and aneurisms was understood, yet, from some unaccountable causes, the practice was never thought of in amputation. Even Fallopius knew of no other means for stopping the bleeding but the cautery. (*De Tum. prætern. p. 665.*) On the whole, the stoppage of bleeding was not attended with a degree of success, proportionate to the advances of the healing art in general. Straps, bands, and compresses were, indeed, put round the member ; but, as the circulation of the blood was not yet correctly known, they were not applied in the proper places ; being arranged either close to the wound, or several of them put at random round the limb. The effect of such immoderately tight, long-continued constriction, could be nothing less than gangrene, and hence

the actual cautery was chiefly employed. The other means for suppressing hemorrhage scarcely merit the name. Terrified at the insecurity and ill-consequences, J. de Vigo (*Practica in Chirurgia copiosa*, 491, Romæ, 1514) and Fabricius ab Aquapendente (*Op. Chir. Venet.* 1619) disapproved of amputating in the sound flesh, and returned to the principle, inculcated by the ancients, of making the incision in the mortified parts. Others endeavoured to lessen the peril of the bleeding by the rapidity with which the limb was removed, and the instantaneous application of the cautery. For this purpose, L. Botalli invented a sort of guillotine, by means of which a member was severed from the body in an instant (*De Curandis Vulneribus Sclopetorum*. Lugd. 1560); while others laid a sharp axe upon the limb, and effected the dismemberment by the blow of a wooden mallet. This barbarous practice was once followed by Fabricius Hildanus, who is called by his countrymen the patriarch and ornament of German surgery, and who, previously to his acquaintance with the use of the ligature, was accustomed to amputate with a red-hot knife, the representation of which is given in his work. (*De Gangrænâ et Sphacelo*, *Op.*) Hildanus became a better surgeon, however, as he grew older, and, in the end, partly contributed to the improvement of amputation, inasmuch as he made the incisions completely in the sound parts, and adopted the method of tying the arteries, as then recently proposed by Paré; though in weak persons he still preferred the actual cautery to the ligature. (*Op.* p. 814.) One of his inventions was a linen bag, or cap, for the stump; and a sort of retractor for holding back the muscles.

By many surgeons, however, the tying of arteries continued to be deemed too troublesome, and hence they persisted in the barbarous use of the actual cautery: of this number were Pigrai (*Epitome des Préceptes de Med. et de Chir.* 8vo. Rouen, 1642), F. Plazzoni (*De Vuln. Sclopet.* 4to. Venet. 1618), and P. M. Rossi (*Consult. et Observ.* 8vo. Francof. 1616). Nay, so difficult was it to eradicate the blind attachment shown to the ancients, that Theodorus Baronijs, a professor at Cremona, publicly declared, in 1609, that he would rather err with Galen, than follow the advice of any other person; and Van Hoorne seems even to have countenanced the detestable machine of Botalli. (*Μικροτέχνη*, p. 75.)

Ambrose Paré, who flourished in the 16th century (*Opera*, Parisiis, 1582), and to whom I have already alluded, made some beneficial innovations in the operation of amputation. It is to his industry, good sense, and skill, that we are chiefly indebted for the abolition of cauterizing instruments, and the general use of a needle and ligature for the suppression of the bleeding. (*Lib. vi. c. 28*, p. 224.)

An anonymous writer has given the following account of the practice and opinions of this distinguished surgeon in relation to amputation. "Paré recommended to cut off the whole of the gangrenous part, if the limb be mortified; but to encroach as little as possible upon the living flesh. At the same time he laid it down as a rule, not to leave a very long stump to an amputated leg; because the patient could more conveniently make use of a wooden leg, with the stump only five finger-breadths long below the knee, than if much more of the flesh were to be preserved. In the arm, however, he left the whole of the living and healthy portion of

the member, only separating the diseased part from the sound.

"In preparing for amputation, he directs the skin and muscles to be drawn upwards, and bound tight with a broad bandage, a little above the part where the incision is to be made. This fillet was intended to answer a threefold purpose: 1st, To afford a quantity of flesh for covering the bone, and facilitating the cure. 2ndly, To close the extremities of the divided blood-vessels. 3rdly, To dull the patient's feelings, by pressure on the subjacent nerves. When this firm ligature has been applied, Paré directs an incision to be made down to the bone, either with a common scalpel, or a curved knife. Then, with a smaller curved knife, we are carefully to divide the muscles, or ligament, remaining between the bones of the forearm, or leg; after which, we may proceed to saw off the bone as high as possible, and to remove the asperities occasioned by the saw.

"With the assistance of a curved pair of forceps, he drew out the extremities of the bleeding arteries, either by themselves alone, or with some portion of the surrounding flesh, to be firmly tied with a strong double thread. He now loosened his bandage, brought together the lips of the wound over the face of the stump, and kept them as close as he could, without actual stretching, by means of four stitches or sutures. If the larger tied vessels should accidentally become loose, he desires the ligature, or bandage, to be again passed round; or else, what is better, to let an assistant grasp the limb firm with both hands, and press with his fingers over the course of the bleeding vessel, so as to stop the hemorrhage; then, with a square-edged needle, about four inches long, and a thread four times doubled, the surgeon must secure the artery in the following manner:—Thrust the armed needle into the outside of the flesh, half a finger's breadth from the vessel which bleeds, and bring it out at the same distance from the bleeding orifice: then surround the vessel with the ligature, pass it back again to within one finger's breadth of the place where it first entered, and tie a fast knot upon a folded slip of linen rag, to prevent its hurting the flesh. By this means, says Paré, the orifice of the artery will be agglutinated to the adjoining flesh so firmly, as not to yield one drop of blood: but if the hemorrhage were not considerable, he contented himself with the application of astringent powders, &c.

"Thus did this famous surgeon endeavour, by his single example and precepts, to exclude the barbarous use of hot irons in amputation. He says, he knew not of any such practice among the old surgeons; except that Galen recommended us to tie bleeding vessels, towards their origin, in accidental wounds: and he thought proper to do the same in cases of amputation. But, in an apology, at the end of his book, Paré has quoted in his own defence a dozen authors, who employed or recommended the ligature before him; and he might have cited many more.

"From the statement we have here given, it may be seen how far the best writers of almost every country have erred in ascribing the original invention of tying arteries to Ambrose Paré. Great merit, indeed, was due to him, for the part he took in extending, and even reviving, this incomparable practice: nay, it is not certain whether any one before him had ever applied the needle and ligature in

similar cases, i. e. after amputation : but how very wide of the truth Mr. John Bell's recent account of this matter is, will appear to every person who will inquire into the facts themselves ; for not only were ligatures and needles in use among the ancients, but likewise the tenaculum, or hook, to lay hold of the bleeding vessels, when they had buried themselves in the muscles. We refer our inquisitive readers to Avicenna, Ætius, Albucasis, Brunus, Theodoric, Guido di Caulico, John de Vigo, L. Bertapælia, Tagaultius, Petrus Argillata, Andreas à Cruce, &c. &c., where they will find enough to satisfy them on this head." (*Rees's Cyclopædia*, art. *Amputation*.)

I shall not here expatiate upon the ill-treatment which Paré experienced from the base and ignorant Gourmelin ; nor upon the slowness and reluctance with which the generality of surgeons renounced the cautery for the ligature. These circumstances may be conceived from what has been already stated. Almost 100 years after Paré, a button of vitriol was ordinarily employed in the Hôtel Dieu at Paris for the stoppage of hemorrhage after amputations ; and Dionis was the first French surgeon who taught and recommended Paré's method. This happened towards the close of the 17th century, while Paré lived towards the end of the 16th. (*Dionis, Cours d'Opérat.* Paris, 1707.)

As Paré, like the rest of the old surgeons, used to cut directly down to the bone, many of the stumps, which he made, must have been badly covered with flesh, and ill fitted for bearing pressure. But all that I have read on the subject of amputation, impresses me with a strong conviction, that, in former times, the projection of the end of the bone, the sugar-loaf form of the stump, the frequent exfoliations, and the difficulty in healing the part, and keeping it healed, were as much owing to the mischief done with the cautery, the rude way of dressing the stump, and ignorance of the method of promoting union by the first intention, as to the mode of operating, or any other circumstance.

What, asks Brünninghausen, was the reason why the ligature of the arteries, which is now regarded by the surgeons of all civilised nations as the best, easiest, and safest method of stopping hemorrhage after amputation should so long have remained unadopted ? Besides the prejudice for the opinions of the ancients already mentioned, another cause was, undoubtedly, the imperfect knowledge of the circulation of the blood,—a correct description of which was first delivered by the immortal Harvey early in the 17th century. (*Exercitatio Anat. de Motu Cordis et Sanguinis in Animalibus.* Francof. 1628.) For some time, this grand discovery met with violent opposition ; but, after it had been acknowledged as an eternal truth, a happy application of it was made to surgery by a French surgeon, named Morell, who, at the siege of Besançon, in 1674, invented the field tourniquet, by means of which more certain pressure was made on the trunk of the artery. By this simple invention, founded, however, on a knowledge of the circulation, the surgeon could at option let the blood of the stump spirt out, or stop its jet entirely ; and now, both during and after the operation, he was first enabled to command the hemorrhage, and coolly and judiciously employ whatever measures were indicated ; for the most

powerful bandages and pressure, previously in use, either stopped the circulation in the whole limb, or could not be made to have the right effect with sufficient quickness. (*Brünninghausen, Erfahr. &c. über die Amp.* p. 36.) Morell's tourniquet, however, was very imperfect ; and it was not till the year 1718, that J. L. Petit, whose name shines so brightly in the history of surgery, invented the kind of tourniquet now employed.

Richard Wiseman, who is justly considered as the father of good English surgery, saw the necessity of making the incision in the sound parts, because gangrene does not always spread evenly, but frequently extends much higher up one side of the limb than the other. He deemed the actual cautery objectionable, as the sloughs were so long in being thrown off. He applied a ligature round the limb, two inches above the limits of the mortification, and, drawing up the muscles, made the incision with a large curved knife, with the back of which he scraped off the periosteum. The bag, or sort of retractor, employed by Fabricius Hildanus, Wiseman thought unnecessary, as the muscles spontaneously drew themselves up as soon as divided. He tied the blood-vessels after the manner of Paré, and deprecated all burning of the stump. After the operation, he drew the flaps over the bone, and either fastened them in this position with stitches, or a tight bandage ; though he generally preferred the former, as the surest means of keeping the end of the bone from protruding. Across the stump he laid a pledget of wax-cerate, and over this a thick layer of Armenian bole and other styptics, and the whole was covered with a bullock's bladder, and a roller applied spirally from the upper part of the remaining portion of the limb, down to the extremity of the stump. On the third day, the dressings were taken off, and a digestive ointment applied. (*Chirurg. Treatises*, vol. ii. p. 220, 8vo. Lond. 1690.)

From this time, amputation may be considered as being an infinitely safer proceeding than it used to be ; for, as we have explained, the ligature of the arteries was now practised and commended in Germany by F. Hildanus, in England by Wiseman, and in France by Dionis. Much, however, remained to be done. The wound was large, and suppurated long and profusely ; the healing was slow ; the ends of the bones perished, and, projecting far beyond the soft parts, retarded the cure so long that the patient was not unfrequently worn out. Hence the best surgeons began seriously to consider what further could be done, with a view of lessening the exposed surface of the wound, and making a better covering of flesh for the ends of the bones.

According to Sprengel, most of the old surgeons preserved a flap of flesh, and he is therefore by no means disposed to regard our countryman Lowdham, as the inventor of this method, though it is acknowledged that the latter surgeon's practice was novel, inasmuch as the flap was formed by making an oblique incision through the integuments from below upwards. (See *James Yonge's Currus Triumphalis e Terebintho*, 8vo. Lond. 1679 ; and *Sprengel's Geschichte der Chirurgie*, b. i. p. 403.) Here, if Sprengel means that many of the old surgeons endeavoured to preserve a partial covering of flesh for the bone, there can be no doubt of its correctness, because we find that they drew back the flesh before they divided

it ; and Celsus and some others even did more ; for, after cutting down to the bone, they detached the flesh further from it upwards, previously to taking the saw : but, on the contrary, if Sprengel wishes us to believe that there were practitioners, who, previously to Lowdham, in the operation of amputation, formed what in England is usually understood by a flap,—that is, a portion of flesh, generally of a semilunar shape, and saved from one side, or both, of the member, for covering the bone,—I cannot see any reason for coinciding with Sprengel's observation. Upon the merit of Lowdham's suggestions, and the practice and principles inculcated by J. Yonge, some reflections, communicated to me by Mr. Carwardine, I insert with great pleasure, as perhaps he is right in thinking that some former editions of this work did not do justice to the memory of the latter writer.

"At the time Yonge wrote (1679)," says Mr. Carwardine, "it was supposed impossible to heal a stump before the bone had exfoliated, and therefore no surgeon would venture upon an attempt at uniting the surface by the first intention. Now, this union by the first intention *was the chief object* of Mr. Yonge in proposing the flap-operation ; and it is to him, and not to Mr. Alanson, who wrote precisely 100 years after him, that we must attribute the honour of this improvement. It is related in a letter addressed to his friend Thomas Hobs, chirurgion, in London, dated Plymouth, August 3, 1678, and published 1679, at the end of his '*Currus Triumphalis e Terebintho*.' It begins thus :—

"Sir, I find by yours that you are surprised with the intimation I gave you, of a way of amputating large members, so as to be able to cure them *per symphysin* in *three weeks* ; and without fouling or scaling the bone. It is a paradox which I will now evince to you to be a truth, after I have first taken notice of what you affirm, that there is a necessity of scaling the ends of those bones left bare after the usual manner of dismembering, before the stump can be soundly cured ; that you never yet found it otherwise, but that, where it hath been attempted, the stumps have apostumated, and the caries come off thereby."

"Yonge then acknowledges, that it was from an ingenious brother, Mr. C. Lowdham, of Exeter, that he had the first hint thereof. He then describes the operation—the laying down the flap over the face of the stump, and sewing it by four or five stitches, &c. After this Yonge proceeds with a methodical enumeration of the advantages of this mode of operating over all others then in use, viz. that it is more *speedy*—the cure not occupying a *fourth of the usual time*—*no suppuration*—*no exfoliation*—less danger of hemorrhage—not liable to break open again from slight injury—and, lastly, much better adapted to the pressure from an artificial leg, &c.

"The foregoing abstract will show (says Mr. Carwardine) how far Mr. O'Halloran's method, in which he dresses the flap and the stump as distinct surfaces, can be regarded as a revival of Lowdham's operation, or whether it has been superseded or improved upon by the *mechanical* ingenuity of the Dutch and French surgeons :—The apparatus of M. De La Faye and Verduin appear to have been merely clumsy and unscientific contrivances for the suppression of hemorrhage. Garengot's operation had also for its object, to

supersede the use of the ligature, which, however, after twelve years' practice, he was obliged to give up, and tie the vessels before he laid down the flap. In the removal of the arm at the shoulder-joint, doubtless the advantages of making a flap from the deltoid, &c., are sufficiently established ; but, in the mode of dressing, I presume that no English surgeon will admit, that the practice of M. Larrey (perhaps the most eminent surgeon that has been formed by the wars of Bonaparte, and whose practice will be hereafter noticed) can supersede the method of Yonge (or Lowdham), who wrote 140 years before him ! Larrey introduces charpie beneath the flap to *prevent* union by the first intention ! Lowdham's object is simply to lay the flap over the wound to prevent exfoliation, and to heal the surface '*per symphysin*' in three weeks." After the receipt of this communication from Mr. Carwardine, I looked over the copy of the "*Currus Triumphalis Terebintho*," preserved in the valuable library of the Royal Medical and Chirurgical Society, and found his statement fully confirmed by the contents of that ancient work. At the same time, I retain the belief, that the example set by Mr. Alanson, with respect to the proper method of dressing stumps, and obtaining a speedy union of the wound, is entitled to the praise of posterity because his advice was so well enforced that it soon produced a revolution in practice ; while the correct suggestions of Lowdham and Yonge, like the hint in Celsus, of the double incision, had sunk into oblivion, or were only known to a few admirers of surgical antiquities.

Mauquest de la Mothe was one of the first who commonly used the tourniquet in amputations, afterwards drawing out the vessels with the forceps and tying them. (*Traité compl. de Chir.* vol. iii. p. 171.) Lowdham's original suggestion of amputating with a flap has been briefly noticed. About eighteen years after Yonge's publication, Peter Verduin, an eminent surgeon at Amsterdam, submitted to the judgment of the profession a new kind of flap amputation. (See *Dis. Epistolica de Novâ Artuum decurandorum Ratione*, 8vo. Amst. 1696.) Two compresses were applied, one under the ham, and the other on the course of the large vessels. The thigh was wrapped in a fine linen cloth, which was sustained by some turns of a roller. This apparatus was covered with a piece of leather, six inches broad, furnished with three straps with buckles, to secure it round the part. The tourniquet was placed in the usual manner. The part, above the place intended to be amputated, was surrounded with a leather strap. The point of a crooked knife, which was made to pass as near to the back part of the bones as possible, was thrust in on one side of the leg, and made to come out on the other. The knife was then carried down, and a flap made of almost the whole calf of the leg. The operation was finished in the ordinary manner. The wound was then washed with a wet sponge, in order to clear it from the fragments of sawn bone. The leather strap, which served to secure the flesh was next loosened, and the flap laid over the stump. The wound was dressed with lycoperdon, lint, and tow, over which was put a bladder, sustained by strips of sticking-plaster. Upon this bladder was placed an instrument, called a *retinaculum*, consisting of a compress, and a concave plate, which were made to press upon the stump by means of two straps, which

crossed each other, and were attached to the broad leather strap surrounding the thigh.

Some excellent precepts on amputation were delivered by J. L. Petit. He improved the tourniquet; and instead of the large crooked amputating knife, formerly employed, first brought into use the straight, more moderate sized knives with sharp backs, now seen in the hands of the best surgeons, because much better calculated than crooked knives for dividing the flesh by a sawing movement, which is the only right and surgical way of attempting to cut any part of the human body. He proved that making the division in the mortified parts was frequently followed by hemorrhage; and for the suppression of bleeding, he thought it the best principle to promote the formation of a coagulum. (*Mém. de l'Acad. des Sciences*, an. 1732, p. 285. See HEMORRHAGE.) For compressing the vessels he employed an instrument which covered the stump, like Verduin's retinaculum, and made pressure by means of a screw. His only objection to Verduin's method was, that the extension of gangrene up the limb frequently hindered the formation of so large a flap. He laid down the valuable general maxim of always removing as much bone, and as little flesh, as possible; for which purpose, he invented what is termed the *double incision*, or dividing the business of cutting through the soft parts into two stages. At some distance below the place where he meant to saw through the bones, he first made the circular cut through the integuments down to the muscles; the skin was then pulled up so as to leave the flesh uncovered to the extent of an inch, and the muscles were now divided at the highest point of their exposure. Lastly, the flesh was held out of the way with a retractor, and the bone was sawn through high enough up to allow of its extremity being well covered with flesh and integuments. The greatest defect in the doctrines of Petit, relative to amputation, was the confidence he put in pressure, instead of the ligature. (*Traité des Malad. Chir.* vol. iii. p. 126.)

The first performance of amputation at the shoulder joint, by Le Dran, and the improvements and alterations of that operation suggested by Garengéot, De La Faye, Desault, Larrey, &c., I shall notice in a future section. (See *Amputation at the Shoulder-joint*.)

Verduin, in his method, formed only one flap. Ravaton and Vermale afterwards thought that it would be better to save a flap from each side of the limb. They were also advocates for tying the vessels, and bringing the two flaps into contact, so as to procure their speedy union, and hinder exfoliations and profuse suppuration. (*Traité des Playes d'Armes à feu*, par Ravaton, 8vo. Paris, 1750; *De La Faye*, in *Mém. de l'Acad. de Chir.* t. v. ed. 12mo.; *Vermale*, *Obs. de Chir.* 8vo. Manheim, 1767.)

The multiplicity of machines, described by Verduin, La Faye, &c., had no other end but that of keeping the flap near the orifices of the vessels, so as to compress and close them. In consequence of the difficulty of making this compression precisely as required, the most considerable vessels between the two bones, when cut, generally becoming retracted, Garengéot determined to employ ligatures.

His first operation of this kind was an amputation of the arm with two flaps. The brachial artery

was tied, and the patient cured without any exfoliations.

Garengéot operated also on a soldier dangerously wounded in the right foot by the bursting of a bomb, which fractured the interior part of the two bones of the leg, and several of the foot: the patient recovered in twenty-seven days. A single flap was made. He rightly preferred dressing and bandaging the stump to the use of the compressing machines invented by Verduin and La Faye; and his choice of a straight knife, instead of a crooked one, was equally judicious.

The preceding case dictated a truth, which will last as long as surgery itself, viz. *that it is advantageous to apply the ligatures in such a manner as to embrace no more than the vessel, so that they may fall off the sooner, and the parts more quickly unite.* (Garengéot, in *Mém. de l'Acad. de Chir.* t. v. 12mo.)

At one time, an objection frequently urged against the foregoing methods, was, that, when the fresh cut flap was immediately laid over the stump, inflammation and abscesses were apt to ensue. Hence, in 1765, Sylvester O'Halloran, a surgeon at Limerick, was led to make the experiment of deferring laying down the flap till the end of the first eight or twelve days after the operation, when it was conjectured that the risk of inflammation and abscesses would be diminished. The tenor of O'Halloran's book is apparently corroborated by the facts brought forward. Here we see one of the grand points insisted upon by our worthy countryman James Yonge, viz. the chance of an immediate union of the wound from laying down the flap without delay, suddenly given up, and because the wound could not always be healed without suppuration, it was determined that it never should do so.

Alexander Monro, senior, disapproved of the tourniquet: he secured the vessels with needles and ligatures; and was the inventor of a bandage, which has been extensively approved of, under the name of Monro's roller. (*Medical Essays of Edinb.* vol. iv. p. 257.)

Bromfield, like Le Dran, restricted amputation to a few cases; and he did not acknowledge its necessity, as a matter of course, in every case of gangrene, much less in every instance of white swelling, or caries. From a passage which I have cited from Dr. Rees's Cyclopædia, it would seem that the tenaculum was known to the ancients; but Bromfield is allowed to be the first modern surgeon who employed this useful instrument. (*Chir. Cases and Obs.* vol. i. p. 41, 8vo. Lond. 1773.)

About the year 1742, the removal of thighs without bloodshed was a subject a good deal broached. A single case, recorded by Schaaarschmid, where a mortified thigh separated without hemorrhage, was the foundation of the scheme. The arteries were completely blocked up, and the parts insensible. (*Haller, Dis. Chir.* vol. v. p. 155.) A similar occurrence was related by Acrel (*Chir. Händels.* p. 557); and Lalouette professed himself a believer in the security from hemorrhage, on account of the vessels being filled with coagula, and therefore he also approved of letting dead parts be removed, or rather fall off, without bloodshed. (*Haller, Dis. Chir.* vol. v. p. 273.)

In cases where the projecting bone of the stump

was affected with necrosis, Bagieu ventured to amputate a second time, and urged a variety of arguments in defence of the practice. (*Mém. de l'Acad. de Chir.* t. ii. p. 274.) He coincided with Le Dran and Bromfield, however, about the propriety of restricting amputation to few cases; and has related numerous examples of limbs being saved, which, according to the doctrines then in vogue, ought to have been cut off. (*Deux Lettres d'un Chir. de l'Armée*, 12mo. Paris, 1750.)

M. Louis, a French surgeon of extraordinary talents, introduced the plan of dividing the loose muscles first; and lastly, those which are closely connected with the bone. He noticed, that the muscles of the thigh, after being divided, were retracted in an unequal degree. He observed, that the superficial ones extending along the limb, more or less obliquely, without being attached to the bone, were drawn up with greater force, and in a greater degree, than others, which are deeply situated, in some measure parallel to the axis of the femur, and fixed to this bone throughout their whole length. The retraction begins the very instant when the muscles are cut, and is not completed till a short time has elapsed. Hence the effect should be promoted, and be as perfect as possible, before the bone is sawn. In amputation of the thigh, M. Louis was always desirous of letting the muscles contract as far as they could: and, for this reason, he was rather averse to using the tourniquet, as the circular pressure of this instrument in some measure counteracted what he wished to take place, and hence, at one time, he preferred letting an assistant make pressure on the artery; though he subsequently expressed his approbation of the tourniquet proposed by M. Pipelet for compressing the femoral artery. (*Mém. de l'Acad. de Chir.* vol. iv. p. 60, 4to.) Actuated by such principles, Louis practised a kind of double incision different from that of Cheselden and Petit, and different also from Alanson's method, which I shall hereafter notice. By the first stroke, he cut, at the same time, both the integuments and the loose superficial muscles; by the second he divided those muscles which are deep, and closely adherent to the femur. On the first, deep, circular cut being completed, Louis used to remove a band, which was placed round the limb, above the track of the knife. This was taken off, in order to allow the divided muscles to become retracted without any impediment. He next cut the deep adherent muscles, on a level with the surfaces of those loose ones, which had been divided in the first incision, and which had now attained their utmost state of retraction. In this way, he could evidently saw the bone high up, and the painful dissection of the skin from the muscles was avoided. Louis was conscious that there was more necessity for saving muscle than skin; and he knew that, when an incision was made at once down to the bone, the retraction of the divided muscles always left the edge of the skin projecting a considerable way beyond them. Hence he deemed the plan of first saving a portion of skin, by dissecting it from the muscles, and turning it up, quite unnecessary. As the bone should always be sawn rather higher than the division of the soft parts, Louis, like J. L. Petit, and most other judicious surgeons, highly approved of the employment of a retractor. He was likewise the author of some valuable instructions for pre-

venting the protrusion of the bone after the operation. (See *Mém. de l'Acad. de Chir.* t. ii. p. 268—410, &c. 4to.) The impartial reader, who takes the trouble to read the remarks on amputation published by this greatest of all the French surgeons of the last century, with the exception perhaps of J. L. Petit and Desault, will be impressed at once with the force and perspicuity of his matter, and with the evident propriety of a good deal of the practice inculcated. Dupuytren often followed the maxim of dividing the skin and loose superficial muscles together.

In England, Cheselden, and not J. L. Petit, is regarded as the surgeon who revived Celsus's method, by having recourse to a *double incision*—that is, by cutting the skin and cellular substance first, and then, by dividing the muscles down to the bone, on a level with the edge of the skin, so that the bone might be sawn higher up, and its end be more completely covered with skin. Whether Cheselden had the priority in this improvement, I cannot presume to say; but he gave an account of it in Gataker's translation of Le Dran's treatise on the operations as early as 1749, which was long prior to the appearance of Petit's posthumous writings; and Cheselden further mentions, that, during his apprenticeship to Mr. Fern, he had communicated to that gentleman his sentiments about the double incision.

In order to hinder the stump from assuming a pyramidal, or sugar-loaf shape, which sometimes happened, notwithstanding every improvement hitherto mentioned, a circular bandage was employed, which acted by supporting the skin and muscles, and preventing their retraction. This bandage, when properly applied, from the upper part of the limb downward, fulfilled in a certain measure the end proposed, though many stumps yet turned out very bad ones. Mr. Sharp was induced, therefore, to revive the ancient plan of bringing the edges of the skin together with sutures; but the pain and other inconveniences of this method were such, that it was never extensively adopted and Mr. Sharp himself ultimately abandoned it. The cross bandage, however, which he used to put over the end of the stump, remains partially in fashion even at the present day. (*Treatise on the Oper.* p. 216; *Critical Inquiry*, p. 268.)

Since the introduction of anæsthesia, and its almost universal employment in surgical operations, the principal objection to the use of sutures, namely, the pain which they occasion, has been removed, and they are now again extensively employed, not only in the union of wounds after amputation, but also after most other surgical operations where accurate apposition and union by the first intention are desired.

The inefficiency of the method of Louis for hindering the protrusion of the bone was asserted by Valentin, who thought the object might be better attained by dividing the parts while they were in a state of tension; for which purpose he recommended changing the posture of the limb, according to the parts which he was about to cut. (*Recherches Critiques sur la Chirurgie Moderne*, 8vo. Amst. 1772.) Valentin's proposal seems never to have excited much attention; whether on account of its inconvenience, or inefficacy, I know not; certain it is, many cases present themselves, in which the posture of a limb absolutely cannot be changed during the operation,

owing to the nature of the disease, or cannot be altered without extreme agony.

About the middle of the 18th century, arose the celebrated controversy about the propriety of amputation in general. Several surgeons now began to be convinced, with Le Dran and Bagieu, that the operation was undertaken on too light grounds; and, in particular, that many bad complicated fractures might be cured without amputation. Such was the doctrine of Boucher (*Mém. de l'Acad. de Chir.* t. ii. p. 304), Gervaise (*Anfangsgr. der Wundarzn.* 8vo. Strasb. 1755), and Faure (*Mém. qui ont concouru pour le Prix de l'Acad. de Chir.* vol. i. p. 100). The latter, especially, urged the prudence of delay in gunshot wounds and comminuted injuries of the bones. But the writer who at this time made the greatest noise in the world, by his general condemnation of amputation, was Bilguer (*Diss. de Membrorum Amputatione*, 8vo. Hal. 1761), whose sentiments received, however, a complete refutation from his own contemporaries, Pott (*Chir. Works*, vol. ii.), Morand (*Opusc. de Chir.* t. i. p. 232), and De la Martinère (*Mém. de l'Acad. de Chir.* vol. iv. p. 1.), and also from later writers, to whom reference will be made in speaking of *Gunshot Wounds*. Even Bilguer himself was compelled to admit the necessity of amputation in cases of gangrene. (*Anweis. für die Feldwundärzten*, s. 170.)

Bilguer's colleague, the celebrated Schmucker, inclined to the same doctrines, and has detailed several cases, where limbs were not only shattered, but actually carried away by balls, yet where a cure followed without amputation. One of his maxims was, that it was better for the member to be taken off by gunshot than by the surgeon's knife, as the ball operated on a healthy subject, the knife on a person debilitated by an hospital. (*Chir. Wahrn.* th. ii. s. 493.) In a later valuable essay on this subject, he restricts amputation to shattered limbs affected with gangrene. His mode of operating was that of M. Louis. He sanctioned joint-operations at the hip and shoulder; but condemned those of the knee and elbow, as never answering. (*Verm. Schrift.* th. i. s. 3.)

Soon after the middle of the last century, the practice of amputating at the joints began to excite increased attention; but, as this is a topic to which I must presently return, it is unnecessary now to dwell upon it. The writings of Puthod, Wohler, Brasdor, Barbet, Sabatier, Park, Moreau, and Vermandois, in relation to this subject, deserve particular notice.

I now come to Mr. Alanson, whose name is as conspicuous in the history of amputation as that of any surgeon yet mentioned. His chief objects were to hinder a protrusion of the bone, and promote union by the first intention. He rejected the band, which was formerly put round the limb for the guidance of the knife, as altogether useless, and an impediment to the quick performance of the circular incision through the skin. When the tourniquet had been applied, an assistant grasped the integuments with both hands, and drew them and the muscles firmly upwards. The operator then fixed his eye upon the proper part where he was to begin the incision, which was made with considerable facility and dispatch, the knife passing with greater quickness in consequence of the tense state of the integuments.

After the incision through the skin had been

made, the assistant still continued a steady support of the parts, while Mr. Alanson separated the cellular and ligamentous attachments with the point of his knife, till as much skin had been drawn up as would, with the muscles, divided in the particular way hereafter recommended, fully cover the whole surface of the wound. Then, instead of applying the knife close to the edge of the integuments, and dividing the muscles in a circular perpendicular manner down to the bone, Mr. Alanson proceeded as follows:—When operating upon the thigh, and standing on the outside of the limb, he applied the edge of his knife under the edge of the supported integuments, upon the inner margin of the vastus internus muscle, and cut obliquely through that and the adjacent muscles, upwards as to the limb and down to the bone, so as to lay it bare about three or four finger-breadths higher than is usually done by the common perpendicular circular incision. He now drew the knife towards himself; then keeping its point upon the bone, and the edge in the same oblique line already pointed out for the former incision, he divided the rest of the muscles in that direction all round the limb: the point of the knife being in contact with, and revolving round the bone through the whole of the division.

According to Mr. Alanson, the speedy execution of the above-directed incision will be much expedited by one assistant continuing a firm and steady elevation of the parts, and another taking care to keep the skin from being wounded, as the knife goes through the muscles, at the under part of the limb. Mr. Alanson censures the old method of depriving the bone of its periosteum to a considerable extent, above and below the part where the saw is to pass, not only as creating unnecessary delay, but since the periosteum serves to support the vessels in their passage to the bone, as apt to produce exfoliations above the part where the bone is to be divided with the saw. Instead of this practice, he recommends first the application of the retractor, as advised by Gooch and Bromfield; and then denuding the bone at the part where the saw is to pass, whereby the bone may be sawn off higher than is usually practised; a material object in hindering a projection of the bone, and forming a small cicatrix.

If the flesh of a stump, formed in the thigh, agreeably to the foregoing plan, be gently brought forward after the operation, and the surface of the wound be then viewed, it may be said to resemble in some degree a conical cavity, the apex of which is the extremity of the bone; and the parts, thus divided, Mr. Alanson thought the best calculated to prevent a sugar-loaf stump.

The part where the bone is to be laid bare, whether two, three, or four finger-breadths higher than the edge of the retracted integuments; or, in other words, the quantity of muscular substance to be taken out, in making the double incision; must be regulated by considering the length of the limb, and the quantity of skin that has been previously saved by dividing the membranous attachments. The quantity of skin saved, and muscular substance taken out, must be in such exact proportion to each other, that the whole surface of the wound will afterwards be easily covered, and the limb not more shortened than is necessary to obtain this end.

After the removal of the limb, Mr. Alanson

drew each bleeding artery gently out with the tenaculum, and tied it as nakedly as possible, with a common slender ligature. When the large vessels had been tied, the tourniquet was immediately slackened, and the wound well cleaned, in order to detect any vessel that might otherwise have remained concealed with its orifice blocked up with coagulated blood; and before the wound was dressed, its whole surface was examined with the greatest accuracy; by which means Mr. Alanson frequently observed a pulsation, where no hemorrhage previously appeared, and turned out a small clot of blood from within the orifice of a considerable artery. He is very particular in recommending every vessel to be secured that is likely to bleed on the attack of the symptomatic fever; for, besides the fatigue and pain, to which such an accident immediately exposes the patient, it seriously interrupts the desired union of the wound. He used always to cleanse the whole surface of the wound well with a sponge and warm water, as he rightly thought that the lodgment of any coagulated blood would be a considerable obstruction to the quick union of the parts.

The skin and muscles were now gently brought forwards: a flannel roller was put around the body, and carried two or three times rather tightly round the upper part of the thigh, as at this point it was intended to form what Mr. Alanson called a sufficient basis, which materially added to the support of the skin and muscles. The roller was then carried down in a circular direction to the extremity of the stump, not so tight as to press rudely or forcibly, but so as to give an easy support to the parts.

The skin and muscles were now placed over the bone in such a direction that the wound appeared only as a line across the face of the stump, with the angles at each side; from which points the ligatures were left out, as their vicinity to either angle might direct. The skin was easily secured in this posture by long slips of linen or lint of the breadth of about two fingers, spread with cerate, or any cooling ointment. If the skin did not easily meet, strips of sticking-plaster were preferred. These were applied from below upwards, across the face of the stump, and over them a soft tow-pledget and compress of linen; the whole being retained with the many-tailed bandage, and two tails placed perpendicularly, in order to retain the dressings upon the face of the stump.

Mr. Alanson censured the plan of raising the end of the stump far from the surface of the bed with pillows, as the posterior muscles were retracted by it; and he considered it best to raise the stump only about a half hand's breadth from the surface of the bed, by which means the muscles were put in an easy relaxed position. The many-tailed bandage Mr. Alanson found much more convenient than the woollen cap, frequently used in former times to support the dressings; and he observes, that, though this seems well calculated to answer that purpose, yet if it be not put on with particular care, the skin is liable to be drawn backwards from the face of the stump; nor can the wound be dressed without first lifting up the stump to remove the cap. (See *Alanson's Practical Obs. on Amputation*, 8vo. Lond. 1779.)

The chief peculiarity in Alanson's method of operating, namely, the mode in which he recom-

mends the oblique division of the muscles to be performed, did not, however, meet with universal approbation; and his extensive dissection of the skin from the muscles was complained of, as excessively painful. The formation of a conical wound, by following Alanson's directions, was regarded by several as impracticable. (See *Marten's Paradoxieen*, b. i. s. 88; *Loeffler, Beytrage*, i. No. 7; *Wardenburg. Briefe eines Arztes*, 2 b. p. 20; *Richter, Anfangsgr.* vol. vii.; *Graefe, Normen, &c.* p. 8; *Hey, Pract. Obs.*) In my opinion, there can be no doubt of the truth of some of the criticisms made by these, and some other writers, on the impossibility of making a wound, with a regular conical cavity, by observing the directions given by Alanson; for if the knife be carried round the member with its edge turned obliquely upwards towards the bone, it will pass spirally, and, of course, the end of the incision will be considerably higher than the beginning. But, though Alanson probably never did himself exactly what he has stated, I am sure that his proposition of making an oblique division of the muscles all round the member has been the source of great improvement in amputations in general. It is true that surgeons do not actually perform the oblique incision all round the limb by one stroke, or revolution of the knife round the bone, as Alanson says that he did; but they accomplish their purpose by repeated, distinct, and suitable applications of the edge of the instrument turned obliquely upwards towards the bone or bones.

Amongst others, Mynors found fault with some of Alanson's instructions, and thought every desideratum might be more certainly attained by saving skin enough, and then cutting through the muscles. The first incision, however, he directed obliquely upwards through the integuments, while they were drawn up by an assistant, and he then cut down to the bone. (*Pract. Thoughts on Amputation*, 8vo. Birming. 1783.)

The removal of limbs without bloodshed, proposed by Guido di Cauliaco in the 14th century, met with modern defenders in J. Wrabetz and W. G. Plouquet. J. Wrabetz, with a ligature which was daily made tighter, took off an arm above the elbow. Into the fissure he sprinkled a styptic powder. On the fourth day the flesh was severed down to the bone, which was sawn through. (*Geschichte eines ohne Messer abgesetzten Oberarms*, 8vo. Freyb. 1782.) Plouquet thought the plan suited to emaciated timid subjects; but not well adapted to the leg or fore-arm. (*Von der Unblütigen Abnehmung der Glieder*, 8vo. Tub. 1786.) The only exemplification of the practice of taking off limbs without bloodshed in modern practice, is sometimes afforded in chronic mortification, where, after the separation of the dead from the living parts down to the bone by Nature herself, the surgeon saws through the exposed bone. In the North London Hospital, an upper extremity, attacked with chronic mortification, was thus removed by Mr. Liston, a little below the axilla, and the patient, a very old woman, recovered.

Some modes of performing flap-amputations, and, in particular, the suggestions and improvements made by Hey, Chopart, Dupuytren, Larrey, Lisfranc, Liston, and other modern practitioners, will be noticed in the description of the amputation of particular members. In the mean time, I shall conclude this section with mentioning the laudable

attempts, made at different periods, to render the patient less sensible of the agony produced by the removal of a limb. Theodoricus administered for this purpose opium and hemlock, and, though he was imitated by many of the ancient surgeons, few moderns have deemed the practice worthy of being continued. The inhalation of stupefying gas has been tried, and so has magnetism. M. J. Cloquet, by some preparatory means not specified by Velpeau, brought a patient into a condition in which the removal of the breast was accomplished without her having been aware of it. (See *Velpeau, Nouv. Elém. de Méd. Opér. t. i. p. 297.*) Guido made the experiment of benumbing the parts with a tight ligature; but a machine, devised a few years ago in England, expressly for the object of stupefying the nerves of a limb previously to amputation, seems freer from danger than some of the means adopted to bring the patient into a stupefied state. (See *J. Moore's Method of preventing or diminishing Pain in several Operations of Surgery*, 8vo. Lond. 1784.) The great reason of the latter plan being given up is, that some patients have made more complaint of the sufferings occasioned by the process of dulling the sensibility of the nerves than of the agony of amputation itself without any such expedient. Yet daily experience proves that the pressure caused on the sciatic nerve by sitting with the pelvis in a certain position will completely benumb the foot and leg, and this with such an absence of pain, that the person so affected is actually unaware of his foot *being asleep*, as it is termed, until he tries to walk.

The above paragraph is interesting as showing the efforts formerly made to alleviate pain during operations. The reader, however, is referred to the article ANÆSTHESIA, for information respecting the more perfect agents, now so universally employed for this purpose.

GENERAL REMARKS ON AMPUTATION.

Amputations may be divided into two classes; amputations in the "*continuity*" of the bones, *i. e.* where the bones are sawn through; and amputations in their "*contiguity*;" or where the limb is separated at one of the articulations. The terms disarticulation and exarticulation are also employed to designate the latter class of operations. The remarks which follow, although they are for the most part applicable to both cases, refer more especially to the former class, and some additional observations on the mode of performing amputation through the articulations will be afterwards offered.

The different steps of the operation, meriting particular attention, are, the choice of the part of the limb where the incisions are to begin; the measures for guarding against bleeding during the operation; the division of the integuments, muscles, and bones, which is to be accomplished in such a manner that the whole surface of the stump will afterwards be covered with skin; tying the arteries, which should be done without including the nerves, or any other adjacent part; placing the integuments in a proper position after the operation; and, finally, the subsequent treatment of the wound.

It is a general rule to amputate as low as the disease will allow; so that as little of the limb may be cut off as possible, the surface of the wound have less extent than would otherwise happen, and the preserved portion of the limb have greater

power in proportion to its length. The longer it is, the better also will it be suited for the adaptation to it afterwards of some artificial substitute.

This rule admits of no exception in the upper extremity. In some parts of the lower limb, however, as will be subsequently explained, it has been customary to select certain situations for the performance of amputation with reference to the future convenience of the patient, even though the disease or injury might admit of the removal of a smaller portion of the limb. But it should always be borne in mind, that the shock which the system sustains at the time, and the subsequent danger to the patient from the various untoward symptoms which may set in while the healing of the wound is in progress, will depend very much on the size of the part removed, and the proportion which it bears to the whole bulk of the body. Amputation, for instance, is unquestionably more dangerous at the shoulder-joint than in the forearm; in the thigh than in the leg; in the upper than in the lower third of the thigh. And when the patient has suffered from long continued disease, and his powers have been already so severely tested, that when amputation is performed the chances in his favour and against him are perhaps nearly evenly balanced, the demand made upon his constitution to heal a larger wound instead of a smaller one may be sufficient to turn the scale, and make all the difference between his death and his recovery.

Here, however, through an imprudent solicitude to obtain the above advantages, let not the surgeon ever be unmindful of the great axiom in surgical operations, that all the diseased parts should be removed; and let him be assured of the truth of what Graefe inculcates, that it is more pardonable to cut away too much than too little. (*Normen für die Ablösung grösserer Gliedm.* p. 60.) At the same time, I do not agree with some modern writers, who deem it necessary to amputate beyond the limits of every abscess and sinus which may extend very far above a diseased joint or compound fracture. Many of these suppurations are only like ordinary abscesses, and finally get well after the main disease or injury is removed, as I have often seen. Were it an invariable rule to amputate above every collection of matter, sometimes five or six inches more of the limb would be sacrificed than circumstances absolutely demanded, and the greater danger of a high, than a low operation, would be encountered. However, in all cases where the bone is suspected to be unsound, or the muscles are affected with the morbid changes peculiar to fungus hæmatodes or other incurable diseases, the operation should be practised sufficiently high to take away all the distempered parts. In secondary amputations, where there has been much suppuration in the limb, and a sinus runs up, Mr. Guthrie says, that if the sinus extend only a short way between the muscles, the membrane lining it may be dissected out; but, if the matter has lain upon the bone, this will have become diseased, and amputation should be practised high enough to remove the affected part of it. (*On Gunshot Wounds*, p. 87.)

Arrest of hemorrhage during the operation is the next point which demands the attention of the surgeon, and to accomplish this the tourniquet is the instrument which is most commonly employed. (See **TOURNIQUET**.)

We know that it was an opinion of the late Mr.

J. Bell, that the flow of blood through a large artery could not be completely stopped by pressure; and the late Mr. Hey adopted a similar notion, in consequence of seeing a case in which the application of two tourniquets to the thigh did not restrain the hemorrhage from a fungus hæmatodes of the limb. He says, the pressure of the tourniquet does not completely obstruct the passage of blood in the arteries; it only diminishes so much of the force of the current as to enable the vessels, *in a sound state*, to exert their natural contractive power so effectually as to prevent hemorrhage. (See *Hey's Pract. Ob.* p. 257, 258, ed. 2.) Of the inaccuracy of this doctrine no man can doubt who sees the femoral artery with its open mouth on the face of a stump, not bleeding while the tourniquet is tight, or skilful pressure is kept up, but throwing out its blood to a great distance the instant the pressure is discontinued. Nor, I apprehend, can any surgeon, who has amputated at the shoulder, and seen how completely pressure commands the flow of blood through the open-mouthed axillary artery, join in the sentiment of John Bell and Hey upon this particular point.

Mr. Liston confirms the preceding statement, observing that pressure complete enough not only to stop the pulsation of an artery in a limb, but also to arrest completely the flow of blood, can be easily applied by means of the fingers only: and, in order to prove the correctness of this remark, he has repeatedly, when no proper assistant was at hand, compressed both the femoral and humeral arteries with the fingers of one hand, whilst, with the other hand, he removed the limb; and this, as he affirms, with the loss of much less blood than if he had followed the ordinary mode. His common practice is to let the pressure be made by an assistant; and in one place, he declares, that he would rather trust to no very efficient assistant than put on a tourniquet. The ease with which the flow of blood through the largest arteries is commanded by manual pressure, is a fact likewise attested by Dupuytren, who only employed the instrument, which he terms the compressor, in a few special cases. (See *Leçons Orales*, &c. t. iv. p. 377; *Elements*, part iii. p. 361; and *Ed. Med. and Surg. Jour.* vol. xx. p. 44.) The following passage explains Mr. Liston's views of this subject: "In all cases, and in all situations and circumstances, hemorrhage can be restrained during the completion of the incisions, and during the employment of means to close the cut ends of the vessels, by means of very slight, but exact pressure on the trunk of the principal vessel. (See also Dupuytren, *Leçons Orales de Clinique Chir.* t. iv. p. 382.) The point at which this should be applied should be at as short a distance as possible above the place of the incision, and at the same time above the origin of any branches which must be cut. Not the slightest pressure should be made until the instant when the incisions are about to be commenced, so that no venous congestion may take place in the limb. All the blood in the limb below the incisions must necessarily be lost. The veins are more easily compressed than the arteries; and pressure made a short time before the operation may arrest the return of blood, whilst it may not stop its influx. Thus engorgement of the lower part of the limb is produced, and the quantity of blood that must be lost is increased. For a similar reason, pressure sufficiently firm to stop

arterial hemorrhage, is to be continued till the principal branches are tied, and then entirely removed; for the continuance of even slight pressure will increase the flow of blood from the surface of the stump—blood flowing in, and being arrested in its venous return, trickles out through the open ends of the veins. If a circular band be used for the compression, such as the screw-tourniquet, it should be put on quickly, screwed up at once, and then the incisions should not be delayed one instant." Baron Dupuytren did not employ the common tourniquet, nor any kind of compress furnished with a handle (see *Leçons Orales*, t. iv. p. 298); he sometimes availed himself of an instrument which he termed a compressor, and which makes pressure on two opposite points of the limb. (See *Leçons Orales*, &c. t. iv. p. 386.)

If, then, the flow of blood through an artery can easily be commanded by pressure, how are we to explain the occasional continuance of bleeding, notwithstanding the pressure of one, or even two, tourniquets? Without doubt, by the fact that the pads of these instruments, when not duly arranged, do more harm than good, by raising the band off the vessel, and perhaps, also, in Mr. Hey's example, by the additional consideration, that tumors of the fungus hæmatodes kind include a large quantity of blood, and will bleed profusely, and for a considerable time after the main supply of blood to them is cut off. The same thing happens in the disease called aneurism by anastomosis, as I have had several opportunities of witnessing, but in no instance more strikingly than in one, where, some time after Mr. Hodgson had tied the radial and ulnar arteries, Mr. Lawrence divided every part of the finger, excepting the tendons and bone, and yet a considerable bleeding went on from the further side of the wound. (See *Med. Chir. Trans.* vol. ix. p. 216.)

The application of the tourniquet is generally left too much to assistants; but so far as my judgment extends, no operator is justified in commencing his incisions before he has examined and fully satisfied himself that the instrument is correctly applied. Mr. Guthrie candidly tells us, that he once lost an officer, in consequence of hemorrhage during amputation of the thigh, although the tourniquet was in the charge of a surgeon of ability; and the advice with which he follows this statement is worth recollecting: "In a case of this kind, where it (the tourniquet) is found of little benefit, the surgeon should not continue twisting and turning it, whilst his patient is bleeding, but quit it altogether, and compress the artery against the pubes." This maxim cannot be too highly commended.

Mr. Guthrie says, "The pad should be firm and rather narrow, and carefully held directly over the artery, whilst the ends of the bandage, in which it is contained, are pinned on the thigh. The strap of the tourniquet is then to be put round the limb, the instrument itself being directly over the pad, with the screw entirely free. The strap is then to be drawn tight, and buckled on the outside, so as to prevent its slipping, and not interfere with the screw, which is to be turned until the pressure is sufficiently forcible to stop the circulation. If the screw require to be turned for more than half its number of turns to effect this, the strap is not sufficiently tight, or the pad has

not been well applied, and they must be replaced." (*On Gunshot Wounds*, p. 204.)

In two amputations at St. Bartholomew's Hospital, I saw the tourniquet break after the soft parts had been divided; and as in one of these cases a good deal of blood was lost, because another tourniquet happened not to be in the room, and pressure on the artery in the groin was not immediately adopted, I coincide with such writers as recommend the rule of always having two tourniquets ready. Graefe even goes so far as to advise putting both of them round the limb before the operation commences (*Normen für die Ablösung grösserer Gliedmassen*, p. 48); but, the frequency of a tourniquet breaking is not so great, as to demand such precaution; and the plan would be objectionable in thigh amputations, where it is a material advantage to have plenty of room between the place of the incision and the band which goes round the limb.

Provision having been made for the arrest of hemorrhage during the operation, either by the application of a tourniquet, or by compression of the vessel by the hands of a trustworthy assistant: the point next to be considered is the division of the soft parts of the limb.

There are two principal methods by which this may be accomplished, by *circular incisions*, and by the *formation of flaps*; but to these may be added modifications by means of *oval* and *elliptical* incisions, which, it will be hereafter seen, combine in some measure the characters of *both* the first-mentioned proceedings.

AMPUTATION BY CIRCULAR INCISION.

In order to make the first cut, the arm is to be carried under the limb, till the knife reaches almost round to the side on which the operator stands. With one sweep, penetrating at least to the fascia, the knife is then to be brought round to the point where it first touched the skin. Thus, the wound is more likely to be regularly made than by cutting first on one side, and then on the other, while the patient is saved some degree of pain, in consequence of the uninterrupted quickness with which the incision is made. Whether the fascia and subjacent muscular fibres be reached or not, is deemed by Velpeau a matter of no consequence; the only essential thing being the perfect division of the skin. (See *Nouv. Elém. de Méd. Opér.* t. i. p. 508.)

The next object is the preservation of as much skin as will afterwards, conjointly with the muscles cut in an oblique direction, cover the end of the stump with facility. It is rather difficult to lay down any other than general principles for the guidance of the surgeon in saving integuments. I am disposed to agree with several modern writers, that the painful dissection of the skin from the muscles has been recommended and practised to a very unnecessary extent,—that is to say, unnecessary, if the division of the muscles be performed in the most advantageous manner. Instead of dissecting back the skin, Dupuytren used to cut all the soft parts at once to the bone, which he next divided, after retracting the muscles. (*Dupuytren, Leçons Orales*, &c. t. iv. p. 297.) However, Langenbeck, another of the most skilful operators on the Continent, prefers detaching the integuments from the fascia for about two finger-breadths (*Bibl. für die Chir.* b. i. p. 567), as is

the common practice in the London hospitals. Some late writers, particularly Mr. Syme, in expressing their preference to muscle as a covering for the end of the bone, seem to forget one fact which I have often noticed, viz. that the muscular cushion, though at first thick and good, soon shrinks to a comparatively small mass. Sir Astley Cooper states that the covering for the end of the bone must be integuments and not muscles; for, if muscular fibres are preserved with the integuments, they will contract, and retraction of the skin covering the stump will be the result. (*Lancet*, vol. i. p. 148.) Brünninghausen also thinks skin a better and more durable covering for the end of the bone than muscular fibres, which after a time dwindle away; and thence he computes the quantity of integuments which ought to be saved, by the measure of the circumference and diameter of the member. Thus, when the limb is nine inches in its circumference, the diameter is about three; therefore, one inch and a half of skin on each side is to be saved. (*Erfahr. &c. über die Amp.* p. 75.) But this author cuts the muscles perpendicularly, so that he is obliged to separate much more skin from the flesh than is necessary when the incision through the muscles is carried obliquely upward. Dr. Hennen and Mr. Guthrie both recommend carrying the knife through the fascia in the first circular incision; and so does Mr. C. Hutchison, who makes no mention of dissecting back the skin, but simply states, that the "integuments and fascia being divided by a circular incision, and retracted upwards, as high as is judged necessary, the superficial muscles should next be divided," &c. (*Pract. Obs. in Surgery*, p. 23, 8vo. Lond. 1816.) We are, therefore, to conclude that he joins Graefe and others in thinking the separation of the skin from the fascia unnecessary. My own observations in practice lead me to believe, that the dissection of the integuments from the subjacent parts used formerly to be carried to an extent beyond all moderation and necessity; and that, as it is a most painful proceeding, and hurtful, by forming a large loose pouch for the lodgment of matter, it ought to be abandoned by every surgeon who follows the method of sawing the bone considerably higher than the first cut through the superficial muscles. Mr. Hey, like Desault (*Œuvres Chir.* t. xxi. p. 545), is an advocate for amputating with a triple incision, and for preserving such a quantity of muscular flesh and integuments as are proportionate to the diameter of the limb. By a *triple* incision, he means first an incision through the integuments alone; secondly, an incision through all the muscles, made somewhat higher than that through the integuments; and thirdly, another incision through that part of the muscular flesh which adheres to the bone, made round that point the bone where the saw is to be applied. The proper distance of these incisions from each other, he says, must be determined by the thickness of the limb upon which the operation is to be performed, making allowance for the retraction of the integuments, and of those muscles which are not adherent to the bone. Supposing the circumference of the limb to be twelve inches where the bone is to be divided, the diameter is about four inches; and, if no retraction of the integuments were to take place, a sufficient covering of the stump would be afforded by making the first in-

cision at the distance of two inches from the place where the bone is to be sawn, that is, at the distance of the semi-diameter of the limb on each side. But, as the integuments, when in a sound state, always recede after they are divided, it is useful to make some allowance for this recession; and to make the first incision, in this case, at least two inches and a half, or three inches, below the place where the bone is to be sawn. As the posterior muscles of the thigh retract a great deal in the process of healing, Mr. Hey advises their division to be begun half an inch above the place where the integuments were cut, and the anterior muscles three quarters of an inch. "The integuments," says he, "will retract a little both above and below the place where they were divided: but the distance from that place must be computed from the mark left upon the surface of the muscles in dividing the integuments." Thus, in fact, in a common thigh amputation, Mr. Hey deemed it necessary to detach the skin from the muscles merely to the extent of half an inch at the back part of the limb, and of three quarters in front; a very different practice from the old custom of making quite a bag of integuments, and turning them back, as the upper piece of a glove is turned down, or rather as the sleeves of a coat are turned up.

This triple incision is well adapted for those parts of the limbs where there is but one bone, as in the thigh and arm; but it is not applicable to the forearm and leg. In these latter situations, it is always necessary to turn back the skin, as a sufficiency of covering cannot otherwise be obtained.

In amputating the thigh at its upper part, Velpeau believes the oblique division of the muscles, with the edge of the knife turned upwards, to be advantageous, as, without this precaution, or the saving and turning back the skin to the extent of two inches, the sides of the wound will not admit of being brought together. (*Nouv. Elém. de Méd. Opér.* t. i. p. 508.) Nor are there many living surgeons who entertain a doubt of the excellence of the principle inculcated by M. Louis respecting the utility of dividing the loose superficial muscles first, and then such as are deeper and adherent to the bone. In fact, a combination of this last method, with the oblique division of the muscles, not exactly by one, but several strokes of the knife, constitutes the mode of performing the circular operation at present most extensively adopted, and sometimes termed, as already mentioned, amputation by a triple incision. Thus, after the skin is cut, and as much of it retracted and saved as is deemed necessary, the operator cuts through the loose muscles at the edge of the retracted skin, first those on the fore part of the limb, and then such as are situated behind. For this purpose, he makes two or more sweeps of the knife, as may be found necessary, carefully directing them obliquely upwards towards the point, where he means to saw the bone. The oblique division of the muscles does not merely enable the operator to saw the bone higher up than he could otherwise do, and to leave, at the same time, more muscle for covering its extremity, but it is a preservation of sound, undetached integuments, which assuredly form the most efficient and durable covering for the stump. I say this, without precisely coinciding with Brünninghausen, who, trusting entirely to skin for covering his stumps, makes an extensive detach-

ment of it from the muscles, and then cuts straight down to the bone. The loose muscles actually cut through now retract considerably, leaving those which are deeper and attached to the bone in a condition to be cut higher up than could have been previously done. Lastly, these are also to be divided with the edge of the knife directed obliquely upwards towards the place where the saw is to be applied. Some operators do more than this; for, after cutting down to the bone, they follow the plan of Celsus, and detach the flesh from its whole circumference upwards with a scalpel, to the extent of about another inch, in order to be enabled to saw the bone still higher up. "*Inter sanam vitiatamque partem incidenda scalpello caro usque ad os, reducenda ab eo sana caro, et circa os subsecanda est, ut eâ quoque parte aliquid ossis nudetur.*" This method, I think, deserves commendation, because it may have considerable effect in hindering a protrusion of the bone, if it does not, in conjunction with the foregoing method of operating, and judicious dressings, render this disagreeable event quite impossible. However, I shall never forget a poor soldier, whose thigh had been amputated in Bergen-op-Zoom, and who was brought about ten days after the operation into the military hospital at Oudenbosch under my care. Not the slightest union of any part of the wound had taken place; abscesses had formed under the fascia on every side of the stump; the loose skin was literally a large bag of purulent matter; the muscles were wasted to almost nothing, and their remains retracted, and shrinking still further away from the extremity of the bone, which protruded at least three inches beyond the soft parts. This unfortunate man had been attacked with chronic tetanus soon after the operation, and, probably, it was to the disturbance of the stump by the effects of that disease, and to the strong and continual tendency of the muscles to retract themselves, induced by this state of the system, that the deplorable state of the stump was to be attributed. He lingered nearly a fortnight in the hospital before he died; previously to which event, large abscesses, communicating with the hollow of the stump, surrounded the greater part of the pelvis. As I had every reason to believe that the operation had been skilfully done, perhaps when I say that the above mode of amputating will make a protrusion of the bone impossible, it is not exactly correct, as the occurrence may sometimes originate from causes which are quite independent of the particular way in which the operation has been executed.

[Instead of the usual circular division some surgeons now make two semilunar incisions on the opposite aspects of the limb. These incisions form the outline of two equal semilunar flaps of integument, which are to be dissected from the subjacent textures and reflected back. This having been done, the muscles are to be cut through opposite the base of the flaps by circular incisions, according to the instructions already given. The flaps should be of sufficient size to meet readily, and without stretching, over the cut ends of the bone and muscles. This differs from the usual operation only in the mode of making the incision in the integuments; it is in principle the same both as regards the division of the remaining soft parts and in the nature of the covering left for the stump. Its advantages are, that the flaps admit of being reflected back with greater facility than the cir-

cular cuff of skin, a matter of some importance if the integument is infiltrated and rigid from disease; and, also, that after the wound is closed, the projecting corners of skin which result from a circular incision are avoided, and the stump has consequently a more rounded and neater appearance.]

All the muscular fibres, on every side, having been cut down to the bone, a piece of linen, somewhat broader than the diameter of the wound, should be torn at one end, along its middle part, to the extent of about eight or ten inches. This is called a *retractor*. It is applied by placing the exposed part of the bone in the slit, and drawing the ends of the linen upward on each side of the stump. In this manner the retractor will obviously keep every part of the surface of the wound out of the way of the saw. Where there are two bones the retractor must have two slits, an inch or an inch and a half apart. The two slits receive the two bones, and the intermediate strip of linen is passed through the interosseous space. Graefe thinks that in amputations of parts where there is only one bone, the unslit portion of the linen should always be applied over the anterior muscles, as these ought constantly to be most evenly kept back, so that no projection of them may interfere with the action of the saw. (*Normen für die Ablösung grösserer Gliedm.* p. 105.) That meritorious surgeon, J. L. Petit, whose name I always mention with pleasure, strongly commends the use of the retractor, the ends of which he drew over the anterior muscles; he says that he has employed this simple and natural means, but that it did not suit the taste of everybody, especially those who consider all the merit of an operation to consist in the quickness of its performance, or who think it satisfactory reasoning to say this is not their method. (*Traité des Mal. Chir.* t. iii. p. 152.) I have seen the saw do so much mischief, in consequence of the operator neglecting to use the retractor, that my conscience obliges me to censure such surgeons as neglect to defend the soft parts by this simple contrivance. There are some who have rejected the use of the retractor, because they have seen it get under the teeth of the saw and obstruct the action of the instrument; but this very circumstance adduced against the retractor is, when considered, the strongest one that could possibly be brought forward in its favour, as the surface of the wound itself, and particularly the edges of the skin, would, in all probability, suffer the same fate as the linen, by getting under the teeth of the saw, if no retractor were employed, in attempting to saw the bone high up, as closely as possible to the soft parts. But, besides defending the surface of the stump from the teeth of the saw, the retractor will undoubtedly enable the operator to saw the bone higher up than he could otherwise do.

Mr. Liston pronounced all kinds of retractors superfluous. Here it should be remembered, that this gentleman's practice was that of flap-amputation, to which he gave the universal preference; a method in which, unquestionably, the retractor may be dispensed with, as, while the saw is acting, one, or both of the flaps can be effectually held out of the way by an assistant. (See *Edinb. Med. and Surg. Journ.* vol. xx. pp. 43—45.) Here, however, I am treating of amputation by the circular incision, in which the retractor is too useful to be relinquished. Were any further authority

necessary in support of the practice of employing the retractor, I might refer to that of Dupuytren (see *Leçons Orales de Clinique Chir.* t. iv. p. 298), whose directions for its application are the following:—If there is only one bone, it is to be placed in the angle of union of the two tails of the retractor, which are to be brought over the anterior surface of the limb, and made rather to cross one another. Thus, the retractor forms a sort of bag covering the wound, and out of the centre of which the bone passes, and becomes the more denuded in proportion as the assistant draws the retractor towards the trunk.

DIVISION OF THE BONES.

In no part of amputation, do operators in general display more awkwardness than in sawing the bone, though, if we except directing the saw against the flesh, the faults are here less pernicious in their consequences than the errors already noticed. At the time of sawing the bone, much depends upon the assistant who holds the limb. If he elevate the lower portion of the bone too much, the saw becomes so pinched that it cannot work. On the other hand, if he allow the weight of the limb to operate too much, the bone breaks before it is nearly sawn through, and its extremity is splintered. It is one of the most common remarks of such persons as are in the habit of frequently seeing amputations, that the part of these operations, which a plain carpenter would do well, foils the skill of a consummate surgeon, and few operators acquit themselves well in the management of the saw. Many of them begin the action of this instrument by moving it in a direction contrary to the inclination of its teeth. Many endeavour to shorten this part of the operation, by making short, very rapid, and almost convulsive strokes, with the saw. Almost all operators fall into the error of bearing too heavily on the instrument. That operator will saw best, who makes the first stroke of the saw by applying its heel to the bone, and drawing the instrument across the part, towards himself, so as to make a slight groove in the bone, which serves very materially to steady the future movements of the instrument; and who makes long regular sweeps with the saw, at first rather slowly than quickly, rather lightly than heavily. The saw is directed by Dupuytren to be applied perpendicularly, and worked in the beginning slowly, but afterwards more quickly, in proportion as the groove becomes deeper, and the risk of the instrument getting out of it is lessened. When the bone is nearly divided, the sawing should proceed with the greatest gentleness. Then the assistants who hold the opposite parts of the limb, should redouble their care to maintain them in their natural directions. (See *Leçons Orales de Clinique Chir.* t. iv. p. 300.) Mr. Liston places himself so that he may grasp the part to be removed during the sawing of the bone, without change of position. He makes the incisions with the left hand free; but, as soon as the saw is in the right, he takes firm hold of the limb below the wound. He disapproves of entrusting the limb to an assistant during the sawing, and lays it down as a rule, that the management of the lower part of the limb should always be left to the person using the saw. The saw, he says, may be worked either horizontally or vertically, but the latter direction seems to him best, because, when

the section is nearly completed, the uncut part of the bone is deep, and less likely to snap on the weight of the limb, or undue pressure, operating downwards. (See *Liston's Elem.* part iii. p. 364.) But there is often a fault in the construction of the saw itself, which impedes its action, quite independently of any fault on the part of the surgeon. I allude to the edge of the instrument not being a little broader than its blade. When the saw is well made, the teeth always make plenty of space for the movement of the rest of the instrument. The saw, recommended by Mr. Guthrie, cuts with both edges, backwards and forwards, which expedites the operation, and (what is of more consequence) helps to prevent splintering when the bone is nearly divided, because the division can be finished by the backward motions, which are the most gentle. (*On Gunshot Wounds*, p. 89.)

If the bone happen to break before the sawing has been finished, the sharp-pointed, projecting spiculum, thus occasioned, must be removed by means of a strong, cutting sort of forceps, termed *bone-nippers*. The perpendicular division of the bone leaves a sharp edge at the extremity of its circumference: it is not the common practice to take any measures for the removal of such sharpness; yet Graefe recommends filing it away (op. cit. p. 66), and Mr. A. C. Hutchison makes it an invariable rule, whether there be any occasion to use the bone-nippers or not, "to take off the asperities, and scrape, or endeavour somewhat to round, the sharp cut edge of the bone with a strong blunt scalpel, in order to prevent the soft parts from being injured, when brought over the end of the bone in forming the stump." (*Pract. Obs. in Surgery*, p. 24.) Though I have not followed this practice, or rather the part of it which relates to cutting off the edge of the bone, I know of no objection to it, unless it be on the score of its inutility, and the delay which it occasions. All projecting points of bone, it is the ordinary custom to remove.

The bone forceps may also be used, instead of the saw, for the division of smaller bones, such as those in the hand or foot.

One proceeding, which seems fit for reprobation, and which, indeed, Mr. Alanson very properly condemned, is the practice of scraping up the periosteum with the knife, as far as the muscles will allow. Nothing seems more probable, than that this may be the cause of the exfoliations which occasionally happen after amputations. At all events, it is a superfluous, useless measure, as a sharp saw, such as ought to be employed, will never be impeded by so slender a membrane as the periosteum. All that the operator ought to do is to take care to cut completely down to the bone all round its circumference. Thus a circular division of the periosteum will be made, and upon this precise situation the saw should be placed. This is the method which was approved of by J. L. Petit. (*Traité des Mal. Chir.* t. iii. p. 159.) It is what I have always done and recommended; yet it must be confessed, that differences of opinion prevail about the necessity, and modes, of dividing the periosteum. Graefe, in common with several others, entertains considerable apprehensions of the effects of the periosteum being torn and lacerated by the saw, exfoliations of the bone and abscesses up to the joint being possible consequences of the rude separation and inflammation of this membrane.

Hence he is an advocate for making a circular cut through it at the place where the saw is to be applied, and then scraping away all below this point in the direction downwards. (*Normen für die Abl. grösserer Gliedm.* p. 105 and 165.) Perhaps no very great objection may lie against this mode, which is not uncommonly followed, though I have some doubts of its real utility, as it scarcely seems practicable in the midst of the oozing of blood to hit with the saw the precise line at which the remains of the periosteum terminate; and, in confirmation of the safety of Petit's practice, Mr. Guthrie's experience may be adduced, who says, "I have often sawn through the bone, without previously touching the periosteum, and the stumps have been as soon healed, and with as little inconvenience as any others." (*On Gunshot Wounds*, p. 88.) A modern author, impressed, like many others, with the fear of tearing the periosteum with the saw, differs from them in thinking it best to scrape the periosteum upwards, by which means, he says, that at least half an inch of this membrane, and a proportionate quantity of muscular fibres, may be preserved for covering the end of the bone, inasmuch as the muscular fibres, adherent to the periosteum, will remain connected with it: an advantage which this author deems very important while the edges of the bone are sharp. In amputation below the knee, he considers the method highly useful, as the sharp edge of the tibia may be not merely covered with skin, but with periosteum and the cellular membrane connected with it. Since his adoption of this practice, he assures us that he has not for a long time seen any exfoliation of the tibia, and never any protrusion of the bone of a stump. (*Brünninghausen, Erfahr. &c. über die Amp.* p. 65, 66, 8vo. Bamb. 1818.) Baron Dupuytren passes the knife circularly through the periosteum close to the retracted soft parts, and then detaches it upwards and downwards with the heel of the knife. (*Leçons Orales de Clinique Chir.* t. iv. p. 299.)

[AMPUTATION BY FLAPS.]

[An account of the invention of this method by Lowdham, and its subsequent adoption and modification by Verduin, Ravaton, and Vermale, has already been given with the history of amputation. Its object is to provide a thick cushion of soft parts to cover the ends of the bones, by preserving flaps composed of both muscles and integuments, instead of integument only, as in the circular operation. This covering may be procured by forming a single large flap on one side, or two equal flaps on opposite sides of the limb. In the ordinary method they are made by transfixing the limb with a sharp-pointed knife, and by cutting the soft parts from within outwards, or from its centre towards its circumference.]

The operation with *one flap* was that originally performed by Lowdham and Verduin in the leg; it is best adapted for situations where the greater bulk of the soft parts is placed on one side of the bones, as in the leg and forearm, but it may be followed with advantage in some of the articulations, in the shoulder-joint for example, and in the fingers. It is also useful in any part of a limb if the soft parts on one side have been so damaged by injury or disease that they are not fitted to form part of the covering for the stump, as in such cases it enables a greater length of limb to be preserved.

The method of amputating the leg with a single flap, cut from the muscles of the calf, which is frequently practised in the present day, is, as nearly as possible, the same as that originally adopted by Verduin, excepting that a straight, instead of a curved knife is now used. Verduin published an account of his operation in 1696, and this has been already referred to in the history of amputation.

The knife is passed through the limb from one side to the other, close behind the bones, and is carried downwards in such a manner that in cutting its way out a semicircular flap is made of sufficient size to cover completely the whole surface of the stump. The angles of this flap are then united by an incision carried transversely (or with a slight convexity downwards) across the opposite half of the limb. Any remaining muscular fibres are then divided transversely at the same level, and the knife is carried between the bones and around each of them in succession, to clear them completely for the application of the saw. Operations with a single large flap, are subject to the disadvantage that the cut edges of skin which are intended to unite with each other do not correspond in their dimensions, the circumference of the flap being much longer than the transverse incision to which it is to be opposed, and some unevenness and puckering is the inevitable result when they are brought together.]

Amputation with two equal flaps, as practised by Vermale, is well adapted for situations where there is a nearly equal bulk of soft parts on opposite sides of the bone. Vermale, after applying the tourniquet, surrounded the part with two red threads, at the distance of four finger-breadths from each other; one at the place where the bone was to be sawn; the other at the place where the incision of the flaps was to terminate. He afterwards thrust a long bistoury down to the bone, at the fore part of the limb; turned it round the circumference, so that it might come out at the opposite part; then, directing the edge of the knife along the bone, he cut down to the inferior thread, where he completed the first flap, which, as the author says, was of a round or conical figure at its extremity. The second flap was made in a similar way on the inferior side of the member. The flaps being held back by an assistant, the knife was carried circularly round the bone to divide any muscular fibres still adhering to it. This method is essentially the same as that which is often practised at the present time, in the thigh and arm. The red threads, however, are dispensed with, and the operator determines with his eye the requisite length for the flaps which ought slightly to exceed the semi-diameter of the limb, supposing two equal flaps are to be made.

[Ravaton formed two flaps by first making a circular incision through all the soft parts down to the bone; he then made a vertical incision on each side leading upwards from the circular incision, and, like it, extending through all the soft parts down to the bone. The two square flaps thus made were then dissected up.

Many surgeons make their flaps more or less square in shape, by keeping the knife close to the bone as it is carried downwards, and then cutting abruptly outwards when a sufficient length has been given to the flap. Any method, however, is objectionable which preserves so large a quantity

of muscle towards the free border of the flaps; since, if this is done, the edges of the skin cannot be brought together over the muscle without considerable difficulty. The most desirable shape for the flaps is that which is obtained by cutting *obliquely* outwards; by this means their thickness gradually diminishes from their attached towards their free border, and the free border has an even and regular semicircular edge. In this way also the surfaces of the flaps as well as their edges will be made exactly to correspond.

Langenbeck preferred to cut the flaps in the opposite direction, or from the skin towards the bone, thinking their shape could be determined with greater certainty in this way. Mr. Luke forms the first flap by transfixion, and the second by cutting from the skin towards the bone. This plan has the merit of obviating one inconvenience which results from making both flaps by transfixion, which is, that the second flap is seldom cut evenly at its edge, for the skin having lost its tension as soon as the first flap is made, is apt to fall in folds under the pressure of the knife, and is more or less notched and mangled in consequence. Mr. Luke transfixes the limb exactly through its centre, whether this be close to the bone or at some distance removed from it, in order that the two incisions in the skin may be exactly equal to each other, but he considers it important that the surfaces should correspond as well as the edges, and should be maintained in contact while the healing is going on. It was for amputation of the thigh that this method was proposed by Mr. Luke, but it seems well adapted for almost any situation, and whether the bones are placed at the centre or near the surface of the limb. Mr. N. Ward, in describing it, says, "Whether it is performed on the thigh, leg, arm, or forearm, the *centre* of the limb should always be taken as the point at which the knife is to be passed in, without reference to the bone or bones. Sometimes the knife will be passed in nearer to the bone than at others, this depending on the relative muscular development of the part operated on." (*Medical Times and Gazette*, Jan. 1852.)]

[AMPUTATION BY THE OVAL INCISION.]

[The oval or oblique incision, described by M. Scoutetten, forms an excellent operation for the shoulder and some other joints, but is not often practised in the continuity of the limbs. It differs from the circular incision, in being made to extend higher up on one side of the limb than on the other, and this extension upwards is commonly made in the direction of the prominence of the articulation, in order to admit of its more ready and complete exposure. At this point the portions of the incision coming from the two sides of the limb, are united to each other, so as to form an angle giving the appearance of an inverted V, the apex of which is over the prominence of the joint, and forms the small end of the oval or *egg-shaped* incision.

For a more detailed description of this mode of amputation the reader is referred to the article on *Amputation at the Shoulder-Joint*, where it will be seen, that it is in some degree a combination of the double flap and circular methods, and possesses many of the advantages belonging to both. (See *Scoutetten sur la Méthode Ovalaire*. Paris, 1827, 4to.)]

[AMPUTATION BY ELLIPTICAL INCISION.]

[The elliptical method, as described by M. Soupart, is not dissimilar in its results to a single flap amputation. An elliptical incision is made round the limb through the integuments down to the muscles. The two ends of the ellipse are of course on opposite sides of the member, and one is necessarily at a considerably higher level than the other. The upper end should be opposite to, or a little below, the point at which the bone is to be sawn, or where the transverse incision would be made in the single flap operation; its lower end should be at the same level as the lower border of the flap would be, in a similar case. The muscles are then to be divided in the same oblique direction from the surface down towards the bone or bones. The result is a single large flap, the edges of which are uninterruptedly continuous with the opposite portion of the incision, instead of forming an angle with it on each side, as in the ordinary method. M. Malgaigne observes that this plan merits a decided preference over the usual operation with a single flap, in those situations where the bones occupy nearly all the transverse diameter of the limb; and where the ordinary operation with a single flap occasions a loss of substance at the two extremities of this diameter; at which point there is all the greater need to preserve the integuments intact, to avoid denudation of the bones. (*Manuel de Méd. Opér.* ed. 5. p. 248.)

From the mode in which its vessels are divided, a flap thus made would also have the advantage of being better nourished than one cut in the usual way by transfixion; and the risk of sloughing, which always attaches, more or less, to a single large flap with a limited basis of attachment, would be considerably diminished.]

[COMPARISON OF THE FLAP AND CIRCULAR METHODS.]

Although the majority of surgeons in England and France (see *Velpeau, Nouv. Elém.* t. i. p. 510), regard the operation by a circular incision as the most eligible under ordinary circumstances, no doubt can exist about the preference which should be given to amputating with a flap, in particular examples. The choice, Dr. Bushe conceives, ought to depend on the state of the limb and nature of the malady. "One surgeon is so devoted to the double circular incision, that he performs no other (method), though his coadjutor in the same hospital is equally bigoted to the double flap operation, and never amputates but after this manner. But the unprejudiced practitioner will look to the nature of the case, and adjust means accordingly." (*Lancet*, No. 246, p. 204.) Notwithstanding the profession of this doctrine, however, Dr. Bushe is in reality very partial to flap amputations, affirming that there is only one part, viz. the upper third of the leg, where he would recommend the double circular incision to be preferred. (*Op. cit.* p. 207.) At the same time, he confesses that when the arm is much emaciated, and flaccid, Dupuytren's mode, with a single circular incision, is that to which he has himself given the preference. He admits, also, the frequency of tedious suppuration and sinuses after flap amputations, which evils, however, he ascribes to the fault of making the flaps too long (p. 206). Flap amputation of the thigh occupies less time than the

circular method, and, I believe, has the important advantage of being less exposed to the danger of a protrusion of the bone. Hence, whenever any reasons exist in the state of the parts or the constitution for apprehending that disagreeable occurrence, it should be preferred. An experienced military surgeon informs us, that, in the first years of his practice he performed several amputations by the double incision strictly according to the precepts of Sabatier, Desault, Pelletan, and Pott, but had the mortification to have three cases in which the bone protruded, though the greatest circumspection was used in the operation and after-treatment. Hence he was induced to make trial of the flap amputation; and, although he imitates O'Halloran in not attempting to bring the flaps close together for the first six or eight days, he reports that the stump is generally healed in twenty or thirty days, and exfoliations rarely happen, on account of the bone being so well covered. In short, he says, that this method is to be preferred to all others. (*J. B. Paroisse, Opusc. de Chir.* p. 135—203, Paris, 1806.) Mr. Syme also states, that though the flap amputations seen by him have been numerous, he has never met with an instance of the bone protruding, or exfoliating after them. (*Ed. Journ.* vol. xiv. p. 38.)

[During the last twenty or thirty years there has been much controversy upon the comparative merits of circular and flap amputations. Mr. Liston was a strong partizan of the method by flaps, and never performed any other operation. He did not even describe the circular method, but said that "its inferiority is so obvious, and so generally acknowledged, that detail of the different steps of the operation is altogether unnecessary. It is more tedious in performance, more painful to the patient, does not afford so good a covering for the end of the bone, and consequently not so convenient and useful support for an artificial limb, and the cure of the wound is protracted. The stump is almost always conical, the end of the bone is, ultimately at least, covered only by integument, and from even very slight pressure this is apt to ulcerate; exfoliation of bone follows to a greater or less extent," &c. &c. (*Elements of Surg.* p. 770.) Messrs. Lizars, Syme, and Fergusson have also almost invariably adopted the flap method, and it has been practised, though not so exclusively, by numerous other surgeons.

The results of more extended experience of the flap operation have failed to establish that decided superiority which some of its advocates have claimed for it; while in answer to the above remarks by Mr. Liston, and in behalf of the circular method, it may now be stated, that rapidity of performance, and the saving of pain to the patient are, since the introduction of anæsthetics, no longer to be considered as recommendations; that it is not true that immediate union is more frequent after the flap than after the circular method; or, if the circular operation is properly performed, that it is more likely to be followed by protrusion of the bone, or conical stump than the method by flap. Again, it is erroneous to suppose that a thick cushion of soft parts will enable a stump to support much pressure, for under no circumstances (excepting after ankle-joint, and, perhaps, also knee-joint amputations, where the osseous surfaces are large, and the integument covering them is dense, and has been accustomed to pressure) will the patient be able to

support the weight of his body on the extremity of the stump; after amputation of the thigh or leg, if the artificial limb is properly constructed, he will never be called upon to do so. Besides this, after a lapse of time, the thick cushion of muscle left in flap amputations degenerates or is absorbed, and the ultimate thickness of the covering differs very little, if at all, in the two cases. It has been objected, on the other hand, to flap amputations that the size of the wound is greater; that more arteries are divided, or that the same artery may be divided in two places, that they are divided obliquely instead of transversely, and that the hemorrhage therefore is more serious and more difficult to be arrested. With respect to the first of these objections, namely, the greater size of the wound, its truth is somewhat doubtful, in fact if the whole surface were accurately measured in two equal-sized limbs, operated upon by the two methods, and if, in the circular method, the entire area of the reflected integument were added to that of the cut extremities of the muscles, the advantage in point of size might even, as was stated by Mr. Liston, be found to be on the side of the flap operation. The majority of surgeons, however, will be disposed to admit the second objection, that there is a greater tendency to hemorrhage, and a greater difficulty in restraining it. It is not that more vessels are *divided*, or that the same vessel is often divided in two places, as has been stated; but more vessels *require ligature*, because they are divided obliquely, and are not so favourably circumstanced for retraction within their sheath, and contraction of their open orifices as when they are divided transversely. Hemorrhage a few hours after the operation is also, and for the same reason, much more frequent with the flap than with the circular method, and it was, in fact, as Sir G. Ballingall observes, to remedy this inconvenience, and to afford facilities for dealing with this sort of secondary hemorrhage, that the practice arose of not bringing the flaps together till some hours after the patient had been placed in bed. Those who speak of additional hemorrhage from the same artery when divided in two places, have overlooked the obvious fact, that however often it may be cut through, it can not possibly bleed excepting from the one orifice which is nearest to the centre of the circulation.

The truth in this, as in most other controversies, has been found to lie between the two extremes, and Mr. Fergusson's comparison of the two methods is worthy of notice, on account of the impartial way in which he recognises the merits of the circular method, although he himself advocates and almost invariably performs flap amputation. He says, "If a circular operation is improperly performed, the whole catalogue of evils may result; but the same may ensue from the method by flap. I do not here speak from conjecture, for I have seen as thorough protrusion of bone after a flap operation as after a circular. If in the circular the incisions are made directly down to the bone—no adequate provision being made for covering its cut end, or if the operator has failed in doing so, then there is no calculating what may follow: if, by the other operation, the flaps are not well made,—too short, and selected from improper parts of the limb—the same evils may ensue. In short, in so far as my experience goes, the evils resulting from one operation may be as great as from the other, according to the manner in which each is performed, the

nature of the coverings, the condition of the parts, or of the constitution; and all, too, must be the result of a badly performed operation by either mode. The latter circumstance constitutes, I believe, the main part of the difference between the two, as a circular operation is much more likely to be ill-done than one by flap; it is in fact a more difficult proceeding, or at all events there is a greater chance of a mistake occurring in the one than in the other." "I deem it" (the circular method) "inferior to the other as regards its execution, but think that it remains to be proved, whether when equal skill and pains are bestowed, and the same mode of dressing is applied to each, the results are so very different as some modern authorities would lead us to believe." (*Pract. Surg.* 3rd ed. p. 197, 198.)

Mr. South says, "I have performed about an equal number of each, and the result has been so nearly the same, that in most cases I hardly think one method is to be preferred to the other." (*Translation of Chelius*, vol. ii. p. 903.) Mr. Skey is inclined to prefer the circular method. He says, "I am much disposed to believe that for purposes of utility and for power of resistance against pressure, the stump made by the circular operation will, in the end, be found preferable." (*Op. Surg.* p. 323.) And he further says, "My colleague, Mr. Stanley, who has frequently adopted the flap operation, has almost entirely abandoned it, as have also Mr. Lawrence, and Mr. Bransby Cooper."

We have given these quotations from several recent authorities, with the view of showing the present state of professional opinion on this controverted question, and have only further to add, that no judicious surgeon should commit himself to an exclusive preference for either one or the other method: it is his duty to acquaint himself thoroughly with the most approved methods of performing *both*, and to adopt whichever may appear to be best suited to the circumstances of each particular case. In many situations, and especially in amputating through the joints, the flap operation is decidedly to be preferred, and in the continuity of the limbs, it may sometimes possess superior advantages. Perhaps the most favourable case for the circular method is when the amputation is performed immediately after an accident, and when the skin is freely movable on the muscles beneath, and can be readily retracted or reflected; while the flap operation is often more convenient in cases of chronic disease, where the parts have become adherent to each other, and are rigid and immovable from infiltration with lymph. In the latter case the rigidity, which would render a circular operation more difficult, enables the flaps to be cut with greater regularity and precision.]

[OF AMPUTATION THROUGH THE JOINTS, OR DISARTICULATION.]

[In these it is more necessary than in ordinary amputations to determine beforehand the exact situation for the incisions, and a more correct anatomical appreciation of the parts is required.

To a surgeon well acquainted with anatomy, the neighbouring prominences of bone will afford the necessary landmarks, and will enable him to determine with precision the exact situation of the articular interspace, and, this being ascertained, to decide upon the position and direction of his incisions. To perform these operations creditably, a

familiar acquaintance with the direction and form of the articular surfaces is also important, or the knife will be liable to become entangled between the bones, and its point and edges will be injured in fruitless endeavours to separate the parts. Special instructions will be given on these points, in speaking of particular amputations.

In other amputations it is a matter of no great importance on which side the surgeon stands; in operations at the joints, however, he should always place himself so that he may hold with his left hand the part to be removed, as he will require to manipulate it himself during the operation, in order to put the ligaments upon the stretch as he is about to divide them with the knife, and to disarticulate the bones when their division is completed.

All the different modes of amputating which have been described may be employed in these operations. The *circular method*, however, is not so often adopted as the flap, or the oval incision, although it answers well in certain situations, in the wrist joint, for example. As a general rule it is not so convenient as the other methods, because it does not admit of so free an exposure of the articulation.

The *methods with double and single flaps* are excellent operations in many cases. Indeed, whatever may be said in favour of circular as compared with flap operations in the continuity of limbs, there can be no doubt that at many of the joints the latter method is very decidedly preferable to the former. In a double flap operation, the joint should generally be opened after the first flap is formed; the ligaments should next be freely divided, and the bone disarticulated, when the knife may be carried through the joint, to complete the operation by the formation of the second flap. It is as well, when practicable, to have the vessels in the second flap, that they may not be divided till the close of the operation, but this is not absolutely necessary: indeed, in the hip-joint, where the danger from hemorrhage is greatest, the anterior flap, which contains the vessels, is usually made first. They can, in fact, either at the hip or shoulder, be effectually compressed before they are cut through by the hands of an assistant, passed into the wound behind the knife while the flap is being made. In a single flap operation, it may sometimes be desirable to make the flap first, then to disarticulate the joint and carry the knife straight out on the opposite side; while, in some cases, the reverse order of proceeding may be preferred; or both incisions may be made before the joint itself is attacked.

The *oval incision* seems to belong almost exclusively to the articulations, being rarely, if ever, practised in the continuity of the limbs. It is one of the best among the many operations proposed for the shoulder joint; and is often practised in the removal of fingers and toes, and of metacarpal and metatarsal bones.

The division of the ligaments and the disarticulation of the bones is perhaps the most difficult part of these operations; and repeated practice on the dead subject, as well as anatomical knowledge, is necessary to enable the surgeon to effect it with precision and dexterity. In a large, loose joint, like the shoulder, there will be no great difficulty, but the case is otherwise in close and complicated articulations, like those of the carpus and tarsus.

The surgeon should throughout the operation hold the part to be removed in his left hand, and, when the joint is exposed, and he has determined in his mind the exact position of the articular interval, he should put the ligaments on the stretch, and then divide them by touching them lightly with the point of the knife. In the application of the knife no force is required; its point only should be used, and its blade should never be allowed to become locked between the articular surfaces. If he knows where to look for the joint, he need never break off the point of his knife or notch its edge, by cutting forcibly and uselessly against the bones.

Amputations at the joints have been advocated by many French surgeons of note, Lisfranc, Blandin, Velpeau, &c., but they have never been much in favour in this country, where they are seldom practised, excepting in the smaller joints of the hand and foot, or when no choice remains, as at the hip or shoulder. Many surgeons hesitate to perform these operations, knowing the serious consequences resulting from wounds into joints, and dreading constitutional symptoms of a similar character. The large open wound made in amputation, however, is not altogether a parallel case to a punctured wound of a closed synovial cavity, and it is, to say the least, extremely doubtful, whether, other things being equal, amputations at the joints are really followed by more serious constitutional irritation than amputation at other parts, while they have the advantage of often permitting a greater length of limb to be preserved. The presence of the articular cartilage is also considered an objection by many, on the ground that adhesion cannot take place between it and the surface of the flap, and that the wound will not heal till it has been absorbed or has exfoliated. In consequence of this idea, it has been recommended that the cartilage should be scraped or sliced away from the bone beneath, and some surgeons, at the present day, in order to remove it completely, even think it better to saw off a thin slice of the bone. The objection, however, has been made on insufficient grounds, for the experience of amputation at the small joints amply demonstrates that the surfaces *can* adhere, and that the wound often heals by the first intention as readily and as rapidly as it could possibly do in any case where the bone had been sawn through. On this subject M. Velpeau remarks, that "it is incorrect to say, with Bécclard and many others, that after amputation in the contiguity, the smooth face of the cartilage does not unite with the flaps, but remains free even after the final cure, unless by some means or another inflammation has been excited. This can only take place by exception. Whether the instrument come in contact with it or not, it nevertheless contracts, and that speedily, firm adhesions with the tissues that cover it, and it is as useless to scrape it with a scalpel as to cauterise it in the manner practised in the time of Heliodorus." (*Velpeau, Op. Surg.* vol. ii. p. 488 of Mott's Translation.)

When, however, the wound does not unite by adhesion, it is perfectly true that the cartilage does undergo removal while the suppurative process is going on; either by gradual disintegration from its free surface, or by a species of necrosis in masses, and separation from its attached surface to the bone beneath.

Dr. Pancoast, of Philadelphia, gives the following

account of the changes which he observed to take place in the cartilage, in a case of amputation at the knee joint, when, from the shortness of the flap, one of the condyles of the femur became exposed. Dr. Pancoast says, "This structure neither reddened nor became painful, so as to exhibit any coating of synovial membrane or other appearance of organisation. It became by the end of a week softened and pulpy on its free surface, in the same manner as occurs when the joint is subjected to the macerating tub of the anatomist. The pulpy lamina which was so soft as to leave a track when rubbed with the end of a probe, *was insensibly removed with the discharges*; by a continuation of the same process of softening and removal, the thin lamina of bone, covering the articular face of the condyles, was completely bared of cartilage in the third week. This lamina first presented a dark gray aspect; some small gray conical elevations soon after made their appearance on its surface, and shortly grew into florid healthy granulations to which, and to other granulations which sprang from the ends of the conical (*crucial*) ligaments, the cutaneous flaps were ultimately firmly united." (*Markoe, on Amputation at the Knee-Joint. New York Journ. of Med.* Jan. 1856, p. 33.)

In another case of amputation at the knee joint, by Dr. Markoe, of New York, on a healthy labouring man, aged 22, it was observed, on the eleventh day after the operation, "that at the bottom of the wound, where the flaps were a little drawn apart by retraction, there was exposed to view about three-fourths of an inch square of the cartilaginous covering of the outer condyle; at first it looked white and shining like healthy cartilage; but gradually the peripheral portion became converted into a soft pultaceous layer of a grayish colour, looking like soaked greasy leather. This change spread in about a week over the whole exposed surface; and in this soft substance granulations rapidly sprung up, which soon converted it into a florid suppurating surface. The exposed cartilage all underwent this change, except a small piece, about as large as a three cent piece, where the transformation seemed to go on under it, and between it and the bone, so that it was detached in a thin layer unchanged. This process was completed about the twenty-second day. On removing the loose sequestrum of cartilage on the twenty-fifth day, it was found to be connected with a larger piece remaining under the anterior edge of the wound. The whole was as large as a shilling piece, and came away easily, leaving a healthy granulating surface beneath." (*New York Journal of Med.* Jan. 1856, p. 25.)

These observations fully bear out the description given by M. Velpeau of the processes by which removal of the cartilage is sometimes effected. (*Med. Oper.* vol. ii. Mott's Translation, p. 488.)

When the cartilage is healthy, then, it does not appear that any advantage is gained by interfering with it; since, even where immediate union does not take place, the delay caused by its separation, need not, judging by the above cases, be of any great moment even in a large joint like the knee; the process having been completed in one at the end of the third, and in the other during the fourth week. On the other hand, the practice of sawing off a thin slice of the bone seems deserving of condemnation, since it exposes a large surface of the cancellated texture, which has suffered more or less

mechanical injury by its division with the saw; and which may possibly necrose or become carious, and give as much or more trouble than the exfoliation of the cartilage could possibly do. But, what is more important, the bone cannot be sawn near its articular extremity without injury to numerous large veins, and the consequent risk of phlebitis and purulent absorption; while this risk is avoided altogether, so far, at least, as the vessels of the bone are concerned, by leaving them covered with a layer of cartilage in a healthy condition, which has not been subjected to mechanical injury, and which is, besides, in itself an inert and nonvascular tissue.]

ARREST OF BLEEDING AFTER AMPUTATION.

After the removal of the limb, the main artery is to be immediately taken hold of with a pair of forceps, or with Assalini's double tenaculum, and tied with a firm, round, smallish ligature. (See LIGATURE.)

None of the surrounding flesh ought to be tied, but the ligature should be placed round the artery, just where it emerges from its lateral connections. The late Mr. Hey was accustomed to tie the femoral artery twice, leaving a small space between the ligatures. Strong reasons against this plan will be found in the article HEMORRHAGE. The smaller arteries are usually taken up with a tenaculum. The tenaculum is not so well suited for the larger arteries, because it readily tears their coats: but it answers excellently for the smaller ones, which it draws out with great promptitude. It has also the advantages of not letting the vessel slip away, as the common forceps does; and of admitting of being held by any body, even a child, while the surgeon applies the ligature; a consideration of importance in places where no professional assistant is at hand. (*Dupuytren, Leçons Orales de Clinique Chir.* t. iv. p. 396.) After tying as many vessels as require it, the best practice is to cut off one half of each ligature, near the knot on the surface of the stump. One portion is quite sufficient for withdrawing the ligature, when this becomes loose; and the other, being only an extraneous body, and productive of irritation and suppuration, should never be allowed to remain.

The plan here recommended is founded upon that valuable principle, which teaches us to lessen, as much as possible, the quantity of extraneous matter in a wound; and as one half of the ligature answers for withdrawing the noose, as soon as loosened, I never follow a method occasionally advised, viz. that of leaving both ends, and twisting them together into one cord, by means of which, when further twisted at the proper period, it is alleged that the detachment may be more quickly brought about.

Dr. Veitch seems to merit the honour of having been the first to set the example of *tying every vessel, the femoral, as well as the smaller arteries, with a single silk thread*, taking care to include, as far as was possible, nothing but the artery; and when this has been done he took off one half of each ligature, as near as possible to the knot, "so that the foreign matter introduced was a mere trifle compared with what I had been accustomed to see." (*Edinb. Med. and Surg. Journ.* vol. ii. p. 178.)

Mr. Alanson directed the ends of the ligatures to

be left hanging out at the two extremities of the wound. But when a ligature is situated in the centre of the wound, it is best to bring it out between the sutures, at the nearest part of the surface; otherwise its running across one half the wound to get at either angle would create a great deal of unnecessary irritation and suppuration.

Baron Dupuytren, and M. Roux declare their preference to the method of bringing out all the ligatures at the lower angle of the wound; the benefit of having them brought out thus low, so as to keep up a drain for any pus that may form, being in their opinion greater than that of arranging them at the points of the wound nearest to them. (*Mém. sur la Réunion de la Plaie après l'Amp.* p. 12.) Dupuytren, who only approved of endeavouring to procure union by the first intention at every point, when amputation had been performed without delay, for a gunshot wound or other bad accident, on a person otherwise healthy, used in all cases to leave the lower part of the wound unclosed. Here he brought out the ends of the ligatures well twisted together into a single cord; and, for the purpose of still farther insuring an outlet for the pus, if the cord was small, he occasionally introduced a small cylinder of charpie into the posterior angle of the incision; for as it was his custom, after circular amputation of the thigh, to bring the sides of the wound partly together (see *Leçons Orales*, &c. p. 416), so as to render the line of it transverse, I infer that he selected the inner angle of the incision as the outlet for the discharge and the place for the cord of ligatures.

As Dr. Hennen observes, the reducing the immoderate size of ligatures, the separating the threads of which they were composed, and placing them at convenient points along the face of the stump, or wound, and the actual removal of one half of each ligature, were amendments very slowly made; "but," says he, "an improvement which appears to me of great consequence was the last of introduction, and is now the slowest of adoption, although, the artery once secured and the value of adhesion duly acknowledged, it is the most obvious of all. I allude to the plan of removing the ends of the ligature altogether, and thus leaving to an extensive wound the greatest possible chance of immediate union." The first printed mention of this practice, as far as Dr. Hennen's investigations have discovered, was in a letter written by Mr. Haire, dated Southminster, Essex, Nov. 1786. "The ligatures," says this gentleman, "sometimes became troublesome, and retarded the cure. An intimate friend of mine, a surgeon of great abilities, proposed to cut the ends of them off close to the knot, and thus leave them to themselves. By following this plan, we have seen stumps healed in the course of ten days. The short ligature, thus left in, commonly made its way out by a small opening in a short time, without any trouble, or the patient being sensible of pain. (See *Lond. Med. Journ.* vol. vii.) Certainly, considering the thickness of the ligatures in use at the above period, this testimony of the success of the method, as Dr. Hennen remarks, is very satisfactory. (*Principles of Military Surgery*, p. 181, ed. 2.) In a letter received by me from Mr. Dunn, surgeon at Scarborough, and dated June 3, 1819, he tells me, "My predecessor, Mr. J. Wilson, the late partner of Mr. Travis, amputated a limb in 1792 or 1793,

and cut off the ligatures close to the arteries, and no trouble ensued. He did this at the recommendation of Dr. Balcombe, of York, who had seen the method practised on the Continent." In September, 1813, Dr. Hennen, who was serving with the army in Spain, began the adoption of this plan, which, he expected, would not only prove useful in promoting immediate union, but in obviating any accidental violence to the ligatures, and the wrong interference of the younger dressers in trying to pull them away. Between September and January, thirty-four cases were treated in this way without any inconvenience following, or the small particles of silk left behind giving rise to any apparent irritation. Dr. Hennen also presented to Sir J. M'Grigor some of the small circles of silk, a part of which had come away with the dressings, while others had floated out on opening the little pustules, which formed over the face of the stump at the points where the arteries had been tied. Some few of the ligatures never made their appearance, and the patients complained of no uneasiness whatever. Convinced of the utility of the method, Dr. Hennen afterwards published an account of it. (See *Lond. Med. Repository*, vol. iii. p. 177, and vol. v. p. 221.) This gentleman subsequently found that Dr. Maxwell, of Dumfries, had adopted the plan as far back as 1798; and Dr. Ferguson, who was at Stockholm during the peace of Amiens, saw it also then followed by some of the surgeons of that city, without any ill effects. (*Hennen's Military Surgery*, p. 175—178. ed. 2.) In July, 1814, Mr. Lawrence communicated to the Medical and Chirurgical Society of London, some cases and observations highly in favour of the practice; and the particularity which he lays much stress upon, is using for the purpose minute firm ligatures, composed of what is called dentist's silk; a material which has been previously recommended by Dr. M'Sweeney in one of the volumes of the *Edin. Med. and Surgical Journ.* (See *Med. Chir. Trans.* vol. vi. p. 156.) In a paper of later date, he says, his further experience had confirmed the usefulness of the method; "that this plan, by diminishing irritation and inflammation, and simplifying the process of dressing, materially promotes the comfort of the patient, and the convenience of the surgeon, while it has not produced ill consequences, or any unpleasant effect, in the cases which have come under his own observation." According to Mr. Lawrence, the small knots of silk generally separate early, and come away with the discharge; where the integuments have united by the first intention, the ligatures often come out rather later, with very trifling suppuration; and, in some instances, they remain quietly in the part. (Op. cit. vol. viii. p. 490.)

When this plan is tried, single strong threads and silk, or rather the kind of ligature which will be described in another place (see *LIGATURE*), should be employed: for, otherwise, the knots would be large, and likely to create suppuration and future trouble. The practice was tried by Delpech at Montpellier; but it is not explained whether he used single threads, or silk, or whether any inconveniences resulted from the method. (See *Rélation d'un Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Anglaise avec la Chirurgie Française*, par P. J. Roux, 3vo. 1815.) Yet candour requires me to state that the method

has gained but few advocates in this country. By Sir Astley Cooper, the practice was found to occasion suppuration, and he therefore gave it up. (*Lancet*, vol. i. p. 149.) Mr. Guthrie, in two or three instances, had also seen some ill-looking abscesses arise from the presence of the bits of ligature, though he approved of the plan where the wound will not unite by the first intention, which, however, can rarely be known beforehand. (*On Gunshot Wounds*, p. 941.) When amputation is performed in crowded hospitals, where hospital gangrene is prevailing, Delpech was an advocate for the plan, because it enabled the surgeon to bring the lips of the wound more perfectly together. By this means, as his experience had taught him, the risk of the wound being infected was materially lessened. (*Chirurgie Clinique*, t. i. p. 83.) The small particles of the ligatures, enclosed in the stump, he says, are discharged at a period when the patient has regained strength enough to be removed into a healthy atmosphere; little openings being produced for their escape, which heal up in twenty-four hours.

Sometimes, the sawn surface of the bone itself bleeds rather profusely. When this happens, it is an excellent plan to hold a compress of lint over the end of the bone, during the time requisite for securing the rest of the vessels. The bleeding from this source will then give no further trouble. At the end of this period, the compress may generally be taken away, the bleeding from the bone having entirely ceased. The surgeon ought not to be content with tying only such vessels as he observes throwing out blood, while the patient is faint with pain; he should endeavour to rouse him from that faintish state by a cordial, and then, wiping off the coagulated blood with a sponge wet in warm water, he should examine narrowly all the surface of the stump; for otherwise he may expect to be obliged by a fresh hemorrhage to undo all the dressings. (*On Amputation of the Larger Extremities*, p. 475, *Monro's Works*.)

When there is merely an oozing from small vessels, Bromfield's advice to loosen the tourniquet completely is highly proper, as this measure, and washing the stump with a little cold water, will put an entire stop to such bleeding, without any occasion for more ligatures. A good deal of blood is sometimes lost from the mouths of the larger veins; and where they bleed much in debilitated subjects, I think Dr. Hennen is right in recommending them to be tied. (*On Military Surgery*, p. 264.) There is no necessity for doing so, however, in ordinary cases; nor should I be disposed to imitate Mr. Hey, who, in consequence of having seen a few instances of bleeding from the femoral vein, generally enclosed that vessel in the ligature along with the artery. (*Practical Obs. in Surgery*, p. 530, ed. 2.) This method was sanctioned by the eminent Desault, who says, that if the vein be left open, and the bandage at the upper part of the limb be too tight, the blood regurgitates downwards, and hemorrhage takes place, as this surgeon assures us he has often seen. When the vein and artery lie close together, as often happens, he recommends one branch of the forceps to be introduced into the artery, and the other into the vein; which being done, the two vessels are to be drawn out together, and included in one ligature; but if they are not so near together, they must be tied separately. (*Œuvres Chir. de Desault, par Bichat*, t. ii. p. 550,

8vo. Paris, 1801.) In the hospitals of London, it is not the usual practice to tie veins, and, except in particular cases, I consider the custom wrong, because a ligature on a large vein sometimes excites a dangerous and fatal inflammation within the vessel, while the intervention of the vein between the one side of the circle of the ligature and the artery, must rather tend to hinder the thread from operating in the most desirable manner upon the latter vessel. For further remarks on venous bleeding during operations, see HEMORRHAGE.

OF DRESSING THE STUMP.

The wound is now to be evenly closed with strips of sticking-plaster, and in general, after circular amputations, in such a manner that the edges of the skin may form a straight line across the face of the stump. This was the mode commended by Alanson, and is what is preferred by the generality of surgeons in this country. Over these plasters and the ends of the ligatures, it is best to place some pieces of lint, spread with the unguentum cetacei, in order to keep such lint from sticking, which becomes an exceedingly troublesome circumstance when the dressings are to be removed. I am decidedly averse to the plan of loading the stump with a large mass of plasters, pledgets, compresses, flannels, &c.; and I see no reason why the strips of adhesive plaster, and a pledget of simple ointment, should not suffice, when supported by two cross bandages, and a common linen roller, applied spirally round the limb, from above downward. The first turn of the roller, indeed, should be fixed round the trunk, while the lower circles secure the cross bandages, often called the Malta cross, over the end of the stump. It is also an excellent method to leave some little interspaces between the plasters, and in summer to keep the linen bandages constantly wet with cold water. In this way, any discharge will readily escape, and the parts, being kept cool, will be less disposed to hemorrhage and inflammation.

Sir Astley Cooper states, that he has seldom succeeded with his stumps above the elbow or knee, when a roller was not employed, which, he says, prevents retraction of the muscles and extensive suppuration. After applying the roller, and bringing the integuments together, he merely puts three strips of adhesive plaster over the wound, and one round the stump, to keep the ends of the plaster in their place: in hot weather he applies a lotion of spirit of wine and water. (*Lancet*, vol. i. p. 150.)

I am completely of opinion with Mr. Alanson, that the elastic woollen cap, sometimes placed over all the bandages and dressings, if not put on with a great deal of care, has a tendency to push the skin backward from the extremity of the stump; and, as it must also heat the part, its employment should be discontinued. In the North London Hospital, stumps are very lightly dressed, and, for the first few hours, Mr. Liston, who always practises flap amputation, merely keeps the flaps together with two or three sutures, and lays over the stump linen or lint wet with cold water. The best position for the stump is that in which it is supported on a small pillow, and moderately raised.

[Points of interrupted suture, at a distance of about an inch from each other, are now very generally employed in the union of wounds after am-

putation, the principal objection to their use, namely, the pain which they occasion, having been removed by the introduction of anæsthetics. If additional support seem necessary, two or three strips of adhesive plaster may also be applied, but as a general rule a light bandage round the limb, and a piece of lint wetted in cold water over the end of the stump, is all that is requisite. The piece of lint can be readily changed without disturbing the wound, and if any hemorrhage take place, it cannot fail to be immediately discovered.]

As a general rule the dressings should not be changed before the third or fourth day, not reckoning the one on which the amputation is performed: by which time, if sutures have been employed, it will be advisable to remove them, though occasionally, if they are not causing irritation, the alternate stitches only may be taken out, and the remainder left for twenty-four or forty-eight hours longer; and Sir Astley Cooper did not change the dressings till the sixth or eighth day; merely removing on the fourth one strip of plaster, in order to let out any confined matter. (See *Lancet*, vol. i. p. 150.) Monro also set down the fifth, sixth, or seventh day, as sufficiently early. He allowed, however, that, if the smell of the wound should become offensive, the outer dressings might be removed sooner. Even when the dressings are to be taken away, it will frequently be found useful to leave one strip of plaster: but the stump must be made clean, and any discharge washed away. These, and other valuable precepts, derived from the eminent Dr. A. Monro, senior, are worthy their great source, and the correctness of them promises to be acknowledged for ever.

The manner of renewing the dressings of stumps is, indeed, a very important business, which should never be intrusted to mere novices; for in removing off the straps of sticking plaster, if great care be not taken, the slight and newly formed adhesions may be torn asunder. Thus, as Mr. A. Hutchison has remarked, if the strap be pulled off by holding one end of it at nearly a right angle with the adhering part, the flap will be raised up with it, and thus a separation of the newly united parts will be produced. "My plan," says he, "is to reflect the raised end of the strap close down upon the adhering parts, and to bring it gently forward with one hand, while the removing part of the strap is followed by two fingers of the other placed upon the skin, &c.; and when one end is detached from its adhesion, as far as the line of incision on the face of the stump, in like manner the other end is brought down and wholly removed." (*Practical Obs.* p. 46.)

In order to facilitate the removal of the plasters and save the patient a great deal of pain, I follow the plan of letting warm water drop over them from a sponge for a few minutes previously to the attempt to remove them. In the early part of the treatment, it is also a valuable rule never to let every strip of plaster be off at once, so as to leave the flesh quite unsupported. Some skill and care are also invariably necessary to avoid pulling away the ligatures with the dressings.

At the end of five or six days, the surgeon may begin to try, in a very gentle manner, whether any of the ligatures are loose; observing rather to twist, than suddenly pull them directly outward. However, he should not use the smallest force, nor persist if the trial create pain. One would hardly

try whether the ligature on the main artery were loose, before the tenth or twelfth day; from the femoral artery it rarely comes away before the expiration of a fortnight. If minute ligatures made of dentist's silk be employed, and both their ends cut off close to the knot, of course, this delicate business of trying to get rid of the irritation of these foreign bodies is entirely superseded.

Though, in the above account, I have directed the edges of the wound, to be brought together in such a way that the wound shall appear as a line across the face of the stump, yet there are instances in which the bone seems most easily and conveniently covered, by making the line of the wound in a perpendicular direction. Mr. B. Bell, indeed, generally approved of it, as affording a ready outlet for matter; it is likewise directed by Sir C. Bell (*Op. Surgery*, vol. i.), by Roux (*Mém. sur la Réunion immédiate de la Plaie après l'Amp.* p. 11), and by Dr. Hennen (*On Military Surgery*, p. 265, ed. 2).

Mr. Hey, referring to amputation of the thigh, has noticed this subject as follows: "the integuments and muscles may be brought into contact by pressing either the anterior and posterior parts, or the sides of the thigh, together. The former method, by the gradual retraction of the posterior muscles, causes the integuments of the anterior part of the stump to cover more completely the extremity of the bone. The latter method causes the integuments and muscles to meet each other the more readily, and therefore is to be preferred when the quantity of soft parts preserved is somewhat deficient." (*Pract. Obs. on Surgery*, p. 533, ed. 2.)

Velpeau states, that the French surgeons prefer having one angle of the wound forward, the other backward, in order that fluids may have a ready outlet. (*Nouv. Elém. de Méd. Chir.* t. i. p. 509; also *Dupuytren*, t. iv. p. 416.) As a general maxim, observes this very distinguished surgeon, the soft parts should be brought together in the direction of the lesser diameter of the stumps, if circular amputations have been performed; and so as to bring the bleeding surfaces of the flaps together, if flap amputations have been done: the wound is to be brought together with its line in the direction of the great diameter of the oval, if the oval or oblique mode of amputation has been selected.

M. Malgaigne observes, that, whether the line of the wound be transverse or perpendicular, the inconveniences are equal. The former plan leaves a *cul-de-sac* below, in which pus lodges; in the latter method, one angle of the wound is pressed against the cushion, which supports the stump. Perhaps, says M. Malgaigne, the oblique direction should be preferred. (See *Malgaigne, Manuel de Méd. Op.* p. 298.)

The plan of bringing the edges of the wound together after amputation, so that they may unite by the first intention, has received, for many years past, the universal approbation of British surgeons. It is their general practice, in the treatment of all incised wounds. It may be said to be the pride of English surgery; for in nothing does it display more convincingly its superiority. Baron Larrey, however, in cases of amputation, disapproves of the attempt to unite the wound by the first intention, and merely brings forward its edges somewhat towards each other with a piece of linen that covers the whole of the wound, and has small holes

cut in it for the passage of the discharge. (*Mém. de Chir. Mil.* t. iii. p. 379.) This piece of linen is supported with a moderately tight roller.

M. Roux, on his arrival in this country, wondered to see British surgeons so prejudiced in favour of union by the first intention, as to adopt it after all amputations. "*C'est pareillement abuser de la réunion immédiate que de l'appliquer en toute circonstance à la plaie qui résulte de l'amputation des membres. J'entends parler de l'amputation dans la continuité des membres, et plus particulièrement encore de l'amputation circulaire.*" (*Parallèle de la Chirurgie Anglaise avec la Chirurgie Française*, p. 128, 8vo. Paris, 1815.) But M. Roux has curiously omitted to explain, in his book, what are the advantages of not bringing the edges of the wound together, and why he calls prejudice the partiality to a method the superior efficacy of which is continually demonstrated in every hospital of London. He does not, indeed, presume to condemn the practice altogether; on the contrary, he allows it to be proper in certain cases; yet he contends that it ought to be confined within particular limits. (P. 130. See, also, *Mém. et Obs. sur la Réunion immédiate de la Plaie après l'Amputation*, &c. 8vo. Paris, 1814.)

In this tract, M. Roux proves most convincingly the benefits of union by the first intention, after amputation of the thigh by the circular incision; but, strangely enough, his prejudices hinder him from advising the practice to be extended to other amputations. He does not positively condemn it in the arm, though he thinks the method less necessary, because amputation there is less dangerous than in the thigh, &c. (P. 45.) To such futile reasoning is this author reduced by the unsoundness of his doctrine. He also deems the attempt at union by the first intention counterindicated, where limbs are amputated for injuries which violently contuse and crush the parts (p. 48), and where the limb is much wasted (p. 50). In the latter condition, however, he thinks Desault's flap amputation may be done, and an effort made to heal the wound by adhesion. In one case, he did this with success (p. 51). The opinions of Dupuytren on this subject lead him also to be an advocate for reform in the practice of aiming constantly at complete union by the first intention, after all amputations. He was for *un sage milieu*. The facts and arguments, which form the basis of his precepts, will be noticed with the subject of union by the first intention in the article WOUNDS.

Dubois has tried the plan with a success equal to that of the London surgeons. "The method is preferable," says Richerand, "to the old one, in whatever point of view it is considered. This union is more expeditious, a few days being sufficient for its completion. Besides the advantage of a quick cure, and such quickness is especially of great importance where the patient has been much reduced, so that he would hardly be able to bear a long suppuration, union by the first intention has the recommendation of saving the patient from a great deal of pain, the flap of integuments with which the bleeding surface of the stump is covered being much less irritating to the flesh than the softest charpie would be, &c.—Three years have elapsed since the publication of the third edition of this book. During this interval, I have performed more than a hundred and fifty amputations, and

the utility of immediate union has been more and more proved to me." (*Nosographie Chirurg.* p. 475, 477, ed. 4.)

But, notwithstanding these and other encomiums on the practice, Richerand, like other French surgeons, is not an advocate for it in certain cases; as, for instance, limbs shattered by gunshot wounds, or affected with hospital gangrene. Here he maintains that it hardly ever succeeds. (P. 473.) But, though it be true, that amputations after gunshot wounds do not generally heal so well as many other cases, it cannot be denied that they do sometimes unite more or less by the first intention; and why should not the chance be taken? It is productive of no danger; there is nothing better to be tried; and if it fail, what is the harm? Why, the wound will then heal by suppuration and the granulating process, just as soon as if the hollow of the stump had been filled with charpie, or left open; it will, in fact, heal in a way, which is less advantageous than union by the first intention, but which is the best which can now happen. The very cases which Richerand condemns as unfit for union by the first intention, are those particularly specified as most favourable for it by Dupuytren (see *Leçons Orales*, t. iv. p. 419); while Delpech is so convinced of the necessity of the perfect closure of the wound, where hospital gangrene is prevailing, that in order to let this object be most completely fulfilled, he advises both ends of each ligature to be cut off close to the knot.

From what has been said, it appears that the practice of healing the wound by the first intention, after amputation, is less general in France than it is in England; a circumstance which may perhaps be explained by the fact of its being much newer to the French than to us. Every improvement must encounter for a time the opposition of prejudice; but one so important as that which we are considering must at length prevail and meet with universal adoption. The observations of MM. Roux and Richerand tend to prove that they are not altogether unaware of its advantages, and they therefore recommend it for certain cases; but their backwardness to extend it to all amputations is little in favour of the comparison which they are so fond of making of French with English surgery. Even the eminent Dupuytren had great apprehensions about lodgments of matter, if union by the first intention were completely attempted; and, for the prevention of them, left the lower angle of the wound open, sometimes placing a tent in it, and always the ends of all the ligatures twisted into one cord, as already explained. This cord of ligatures serves to conduct the discharge out of the unclosed angle of the wound, and abscesses in the deep part of the stump are prevented. A great portion of the wound unites by the first intention; suppuration only takes place in the track of the ligatures, and, in general, as soon as these have been detached, it soon ceases. (See *Leçons Orales*, t. iv. p. 416.)

However, that stumps may fall into a state in which the pressure of all plasters and bandages whatever should be most carefully avoided, and emollient poultices used, is a truth of which every surgeon of experience must be fully convinced. This happens whenever the parts are affected with considerable tension, inflammation, and swelling, or painful acute abscesses. There is also no utility in keeping the edges of the wound very closely

compressed together when all chance of adhesion is past, and the parts must heal by the granulating process. My friend Mr. Guthrie, after amputations performed from necessity in parts not in a healthy state, as in most secondary amputations after compound fractures of the thigh, does not insist upon the edges of the wound being brought into close contact by sticking plaster, compress, and bandage. In these cases, he also recommends the bone to be sawn an inch shorter than usual, or than would be necessary under other circumstances, in order to prevent its protrusion, and the ligatures to be cut off close to the knots, so as to lessen irritation. The integuments and muscles are to be brought forward, and retained so by a moderately tight roller, but not laid down against the bone. Some fine lint, smeared with cerate or oil, is to be put between the edges of the wound: and a piece of linen and a Malta cross over it, supported by a few light turns of the roller. "In some cases," says Mr. Guthrie, "I have put one, and even two straps of plaster over the stump, to keep the edges approximated, without being in contact, and where the parts are but little diseased this may be attempted; but, if the stump becomes uneasy, they should be cut, and a poultice applied. When only a part of the stump has appeared to slough, I have found the spiritus camphoræ alone, or diluted with a watery solution of opium, applied with the lint, very useful." (*On Gunshot Wounds*, p. 104.)

The reasons which led Mr. Guthrie to incline to the plan of not bringing together the edges of the wound, in cases of this description, must be learned by reference to his own valuable work. His cases and arguments are entitled to serious consideration; and though they, as well as the observations of M. Roux (*Mém. sur la Réunion immédiate de la Plaie après l'Amputation*, 8vo. Paris, 1814), leave me unconvinced of the usefulness of not bringing the edges of the wound together immediately after the amputation of bad compound fractures, there are some of his observations, respecting the injurious effects of pressure in certain conditions of the stump, perfectly agreeing with my own sentiments. At present, I have never seen any case of amputation, in which I should not have thought the surgeon wrong, had he not brought the sides of the wound together directly, or within a few hours after the operation, so as to afford the chance of union by the first intention.

VARIOUS BAD CONSEQUENCES MAY FOLLOW AMPUTATION;

As, for instance, spasms of the stump, tetanus, hemorrhage, severe inflammation of the stump, abscesses and extensive sinuses, inflammation of the medullary membrane, necrosis (see *B. Phillips*, in *Lond. Med. Gaz.* for 1833—34, p. 189), protrusion of the bone, phlebitis, and suppuration in internal organs, and in various other parts of the body, hospital gangrene, neuromata, &c. Of these several complications, which may either interrupt cicatrization, or subject the patient to great and protracted suffering, or even lead to a fatal termination, some are common to many operations; others restricted to that which is now under consideration; some arise from external causes; others from internal. (See *Dupuytren, Leçons Orales*, t. iv. p. 425.) It is only necessary to enter into a part of these topics in the present place, because the others more properly belong to the articles HOSPI-

TAL GANGRENE, NECROSIS, PHLEBITIS, PYÆMIA STUMPS, SUPPURATION, and TETANUS.

SECONDARY HEMORRHAGE.

Bleeding, after the operation, is of two kinds in regard to the time when it occurs. The first takes place within twenty-four hours after the operation. Hence an assistant should always be left with the patient, with directions carefully and repeatedly to look at the stump, and if any bleeding should arise, to apply the tourniquet until further aid be obtained. In case no assistance can be spared for this purpose, as must frequently happen in country practice, the tourniquet should be left slackly round the limb, and the nurse, or patient himself, directed to turn the screw of the instrument, in order to tighten it, in case of need. A slack tourniquet, left round the limb after amputation, cannot do harm, and its not having been ready in this way has cost many patients their lives.

If the bleeding should not be from an artery of consequence, the application of linen dipped in cold or iced water will sometimes check it, and the disagreeable necessity for removing the dressings and opening the wound may thus be avoided. But it often happens that the wound must be opened, and the bleeding vessel tied. This is a very painful proceeding; for when the dressings have been applied some hours, and the stump has had time to inflame, nothing can exceed the suffering to which the patient is subjected by their removal. Here we see the prudence of being particularly careful at first to tie every suspicious vessel.

A few years ago, directly after the ligature of the vessels, the stump was always closed and dressed. Such, indeed, is still the general practice. Dupuytren deviated from this custom by letting one or several hours elapse before he dressed the stump. The vessels having been secured, the patient was conveyed into bed again, with merely a single compress and slack bandage placed on the stump. Dupuytren's reasons for this practice are that, notwithstanding every possible attention, hemorrhage will frequently take place shortly after operation, and compel the surgeon to remove the dressings; and that these often conceal the bleeding, till it has gone on to a fatal extent. Arteries are frequently prevented for a time from throwing out blood by the patient's syncope or mental depression; but, in two or three hours, they begin to bleed profusely, on the circulation recovering its force. From the period when Dupuytren commenced the custom of deferring the dressing for a time, no consecutive hemorrhage of this kind occurred in any of his patients. (See *Leçons Orales*, &c. t. iv. p. 412.) The regular dressing of stumps is also deferred by Mr. Liston for six or eight hours, or till all oozing has ceased; merely lint wetted with cold water being at first placed over the wound. (See *Liston's Elem.* part iii. p. 368.)

The second sort of hemorrhage, after amputation, arises from ulceration of arteries, and may occur a few days, or even some weeks or months, after the operation, when all the ligatures have come away, and the patient seems nearly well. Two such cases are related by Mr. Bromfield. (Vol. i. p. 307.) J. L. Petit saw an instance in which the hemorrhage came on twenty days after amputation of the thigh very high up; and Baron Dupuytren refers to an example in La Charité, where the bleeding took place two months after an

amputation of the leg, from a fistulous opening in the stump, in consequence of ulceration of one side of the popliteal artery. (See *Leçons Orales*, &c. t. iv. p. 426.) Now that the plan of covering the stump with sound skin is adopted, this kind of bleeding is less common than formerly. When the bleeding vessel is large, there is no chance of putting the patient out of danger, except by cutting down to the vessel, and tying it. The trunk of the vessel, however, may sometimes be more conveniently tied than the bleeding branch itself.

Mr. Hey mentions a particular sort of hemorrhage after the operation: "I have seen," says he, "a few instances of the integuments becoming so contracted after the operation, as to compress the veins just above the extremity of the stump, and bring on after some hours a copious hemorrhage. When it has appeared clear to me that the hemorrhage was venous, I have made a division of integuments on one side of the thigh, sufficient to remove the stricture, and this method has immediately suppressed the hemorrhage." (P. 530, edit. 2.)

I have never met with a case where hemorrhage was unequivocally produced by a contraction of the integuments. Dr. Hennen states that he had seen only one example, and it was successfully treated by loosening the bandage, and moistening the dressings with cold water. (*On Military Surgery*, p. 264, ed. 2.) Here I infer, from the mode of relief, that the cause was not the pressure of the integuments, but that of the roller on the veins.

In Mr. Guthrie's practical work there are some excellent remarks on those hemorrhages, which, in an irritable and sloughing state of a stump, frequently take place from the small branches, or from the main trunks of the arteries, in consequence of ulceration. It is (says he) not always easy to discover the bleeding vessel, or, when discovered, to secure it on the face of the stump; for, as the ulcerative process has not ceased, and the end of the artery, which is to be secured, is not sound, no healthy action takes place. The ligature very soon cuts its way through, or is thrown off, and the hemorrhage returns; or some other branch is opened, and another ligature is required, which is equally uncertain; and, under this succession of ligatures and hemorrhages, the patient dies. Here, cutting down to the principal artery, in preference to another amputation, has often succeeded; but, under other circumstances, it fails, and amputation becomes ultimately necessary. At the same time it is allowed that this operation may also fail. On the whole, Mr. Guthrie professes himself to be an advocate in most cases for tying the artery in the first instance; and if this proceeding should not answer, he would then amputate. However, the practice of taking up the artery, he thinks, should not be adopted indiscriminately, the doctrines of aneurism not being here applicable, because there is a wounded vessel, with an external opening. "In the thigh, the operation is less certain than in the arm, and especially if it is not the main artery that bleeds; for the branch from which the hemorrhage proceeds may come from the profunda, and tying the artery in the groin on such opinion would be doing a serious operation, and one which probably would not succeed; for, the anastomosing branches would restore the circulation in the stump in a short time, and again establish the bleeding. If it is the femoral artery that bleeds, and the

ligature is applied high, it is very liable to a return of hemorrhage. To obviate these difficulties, the part from which the bleeding comes should be well studied, and the shortest distance from the stump carefully noted at which compression on the artery commands the bleeding; and at that spot the ligature should be applied, provided it is not within the sphere of the inflammation of the stump." (*On Gunshot Wounds*, p. 105, 106.) Thus far the advice seems to me correct and valuable; but, where the hemorrhage could be restrained by taking up the artery in the groin, though not lower down, I doubt the propriety of preferring amputation to this other less severe operation, provided the efficiency of a ligature above the profunda be proved in the manner judiciously recommended by Mr. Guthrie, viz. by means of pressure.

Inflammation and suppuration in the arteries of a stump have a particular tendency to loosen the clot in them, and thus produce secondary hemorrhage. Ulceration of an artery may also be excited by an inflammation, which keeps up suppuration directly around the vessel. At the period when the ligatures are expected to be detached, the utmost vigilance should always be exerted to guard the patient from the risk of secondary hemorrhage. (See *Dupuytren, Leçons Orales*, t. iv. p. 428.)

These kinds of secondary hemorrhage, as Baron Dupuytren justly observes, are much more difficult to stop, than such as come on immediately or soon after amputation. The cellular tissue is deprived of its natural suppleness and flexibility; and is so thickened and changed that every fresh ligature cuts through it. Generally, also, the direct application of a ligature to the bleeding part of the arteries is impracticable; because, as the coats of the vessel adhere to the neighbouring textures, it either cannot be taken hold of, or is torn with the least effort being made with the forceps to draw it out. As for permanent compression, this is frequently ineffectual, and attended with too much pain. Under these circumstances, it is better to expose and tie the principal artery at some distance above the stump. (*Op. vol. i. cit. p. 429.*) Thus, in a case of secondary hemorrhage after amputation of the leg, where the bleeding returned notwithstanding the repeated application of the ligature, and even the actual cautery, Baron Dupuytren took up the femoral artery in the upper third of the thigh, and the result was perfectly successful. The same practice has succeeded with others. Mr. Liston informs us, that he has had recourse to it in many cases, and uniformly with success. (See *Elements*, part iii. p. 371.) This gentleman notices a kind of secondary hemorrhage, which does not consist in an arterial and rapid flow, but in a slow and continual oozing from the dark ulcerated cavities round the end of the bone. This case is ascribed by Mr. Liston to diseased action in the cancellated texture of the bone; and the treatment which he recommends is that of removing the coagula, filling the cavity with lint, and applying firm pressure. (See *Liston's Elem.* part iii. p. 372.)

ON PROTRUSION OF THE BONE.

It appeared to M. Louis, that this disagreeable consequence may generally be prevented by taking care to divide the loose muscles first, and after their complete retraction, unresisted by any band or tourniquet, by observing to divide with a bistoury the muscles which adhere to the bone. By

this method, the bone may be sawn considerably higher than it could be if no attention were paid to beginning with the division of the loose muscles, and concluding with that of others attached to the bone. M. Louis argues, that the protrusion of the bones will never take place, so long as they are immediately encompassed with the fleshy substance of the muscles: this proposition is incontestable. But, with regard to another assertion, that whether the skin saved by the operation be long or short is a circumstance that has no influence in preventing or promoting the protrusion, I believe that this part of his statement is less correct. (See *Mém. sur la Saillie de l'Os après l'Amputation*, in *Mém. de l'Acad. de Chirurgie*, tom. v. p. 273, edit. in 12mo.)

As Mr. Guthrie has observed, a protrusion of the bone, after sloughing of the stump or other accidental circumstances, will sometimes happen, without any fault on the part of the operator; but he thinks it may almost always be prevented by attention to the following rules:—1. To leave the integuments attached to the muscles, instead of turning them back. 2. When the muscles are cut through in a slanting direction, upwards and inwards, or even directly downwards, to separate them from the bone, so that it may appear at the bottom of the cone as a depressed point. 3. To cut the bone short, and to keep the limb constantly bandaged from the trunk during the cure, so as to prevent the retraction of the muscles. If a surgeon find, directly after the operation, that the bone cannot be well covered, he should immediately saw off as much more of it as will reduce it to its proper length. The error may be remedied at this moment with very little inconvenience, in comparison with what must afterwards be encountered if the opportunity be neglected. (*On Gun-shot Wounds*, p. 109.) This last piece of advice perfectly agrees with the view which I entertain of the subject.

When the end of the bone protrudes, it of course hinders cicatrisation, and becomes itself affected with necrosis. By the process of exfoliation, the dead portion of bone is sometimes thrown off, and a cure follows. But, in general, this desirable change is extremely tedious, and the result uncertain; because it frequently happens, that, after the piece of bone has separated, the rest yet projects too much, and the stump still continues too conical to heal firmly enough to be capable of bearing the necessary pressure. When, however, the end of the bone forms only a slight projection, and the stump is not too conical, it is always best to leave nature to throw off the redundant exfoliating portion. In the opposite circumstances, the removal of all such parts of it as cannot be covered by the integuments is the best practice, and, if well executed, will effect a cure.

The second operation is exceedingly unpleasant to the surgeon, because patients are apt to suspect, and not without reason, that the first was not properly managed. Let me therefore repeat, that the surest way of avoiding the evil is to cut the deep muscles rather higher than the superficial ones, as inculcated by M. Louis, by which means the bone will certainly lie within the level of the surface of the divided flesh. If the soft parts are found to be deficient, let another piece of the bone be exposed and sawn off at once, before the patient is removed from the operation table.

[Sometimes, although a sufficiency of covering may have been left in the first instance, a portion of bone will become necrosed, in consequence probably of the mechanical injury it has suffered, together with its periosteum and medullary membrane, from the application of the saw. In such a case, notwithstanding the end of the bone may have been well covered at first, it will often ultimately protrude, in consequence of the gradual retraction of the soft parts during the long delay in the healing process, which is the necessary result of the presence of the dead piece of bone. In a case of this kind, where we may infer the protrusion to be the consequence of the necrosis, rather than the necrosis of the protrusion, it will obviously be better to leave the separation to the efforts of nature.]

Mr. Syme believes that it is not the local injury which is alone concerned in causing death of the bone after amputation, but that inflammation of the medullary membrane may cooperate, if it does not sometimes act exclusively, in its production. The most conclusive evidence in support of this opinion, he remarks, is presented by those conical-shaped exfoliations, extending up the interior of the bone, sometimes to the length of several inches, which are occasionally extracted from stumps. Mr. Syme has one in his possession, extracted from the humerus, which is five inches in length. He believes further “that if the medullary membrane be liable to inflammation, suppuration of its texture and inflammation of the veins cannot fail to be the frequent consequence, especially in hospitals where, notwithstanding every precaution, certain descriptions of injuries will always be apt to excite phlebitis and other forms of spreading inflammation. But when the bone is divided through the condyles” (he is speaking of amputation just above the knee joint) “nothing more than the epiphysis being concerned, the medullary membrane is not at all disturbed, while the cancellated texture is not liable to exfoliate, either from its proneness to die from injury, or through inflammation of any other texture.” (See *Ed. Monthly Journal*, May, 1845, p. 537.) So impressed was Mr. Syme with these opinions, that he thought it preferable in all cases to amputate through the cancellated extremities of bones, and he believed it to be an error to divide the thigh bone through its shaft instead of through the condyles or trochanters.

These views may be correct so far as regards necrosis of the bone, which is probably less likely to occur in the cancellated texture on account of its greater vascularity; but with respect to the risk of phlebitis being lessened by amputating in the immediate neighbourhood of a joint, this must be extremely problematical; on the contrary, we should expect that the danger would be increased, on account of the large number of veins always distributed within the articular extremities of the bones; and, moreover, if injury to the medullary membrane has anything to do with the production of phlebitis, the risk must also be greater from this cause in the cancellated texture, since every cell is lined by a membrane continuous, and in every respect identical, with the medullary membrane of the shaft.

It is necessary, however, to state that Mr. Syme, having become dissatisfied with the results of his amputations through the condyles of the femur, has since ceased to perform this operation or

to resort to amputation through the trochanters as a place of election; having satisfied himself "that the operation by circular incision, if performed with due care, on proper principles, may be employed in the lower third of the thigh safely and advantageously." (*Ed. Monthly Journal*, Nov. 1846, p. 225.)

Dr. Markoe does not agree with Mr. Syme, in attributing the formation of the tubular sequestra above alluded to, to inflammation of the medullary membrane, though he admits this as a possible explanation. He regards them "as produced by the severing of the nutritious artery of the bone, either by the saw, while it is passing through its bony canal, or by the catlin before it has reached the nutritious foramen. The supply of blood," he observes, "thus cut off from the medullary membrane, can only be restored by the anastomosis which it has with the vessels of the spongy portion above. These vessels, however, are contained in unyielding canals, and the necessary increase in their calibre can take place but slowly; in the meantime therefore, the small vessels which the medullary membrane sends into the bone are not properly filled, and the death of the bone is produced up to the points where the anastomotic supply is sufficient to save it." (*See N. Y. Journ. of Med.* vol. xvi. 1856, p. 41.)

These observations are made by Dr. Markoe with reference to the thigh bone, where, it will be remembered, the direction of the canal for the nutritious artery is invariably from below upwards, but the explanation loses much of its value when we consider that these sequestra form also in the humerus, in which bone the nutritious artery has, with equal constancy, an exactly opposite direction.]

SPASMS OF THE STUMP

Constitute another afflicting occurrence, as they put the patient to the greatest agony, tend to cause a protrusion of the bone, or sugar-loaf stump, and in some cases extend to the whole body, and ultimately prove fatal. But this unfortunate affection, which was rather frequent after amputations performed in the ancient manner, is infinitely less so, after the modern improved plans of operating, tying, the vessels, and dressing the wound. When, however, it does occur, the stump must be kept from starting, by binding it down with a broad band, placed across it a little way above the wound. The flesh is to be properly supported with a bandage applied from above downwards, and opiates should be liberally exhibited.

OF NEUROMATA AFTER AMPUTATION.

Sometimes amputation has been found necessary a second time, in consequence of a morbid protuberance of the nerves of the stump, — a change noticed by Molinelli, Morgagni, Lower, Arne-mann, and Prochaska, and always attended with excruciating pain and great irritability of the part, and sometimes with retraction of the skin and protrusion of the bone. According to Mr. Liston, neuromata are more frequent after amputation of the arm and forearm than other amputations. The disease seems to him however, to be less common than formerly, which he refers partly to flap amputations having been more extensively adopted, and partly to the method of tying arteries, so as to include nothing else in the ligature. In the forearm I have never seen a neuroma follow amputation,

and yet almost all the operations were circular. Sir Astley Cooper, in his Lectures, relates one instance of such a stump high up the arm, where, upon examination of the part near the axilla, a tumor was felt, which, when touched, made the patient jump as if he had been electrified. In this case, as the bone protruded, amputation at the shoulder was performed. In another example, where a leg-stump was in a painful irritable state from a similar cause, Sir Astley Cooper effectually relieved the patient by removing the diseased end of the posterior tibial nerve. This plan should always be preferred to amputation, when it presents any chance of being efficient. In a third instance, amputation was repeated at the patient's desire, and the nerves were found enlarged, forming a ganglion which partly rested upon the extremity of the bone. Such a degree of irritation had been produced by it, that no part of the stump could be touched without exciting a kind of electric shock. In a case that occurred in the Middlesex Hospital, amputation of the thigh was performed a second time, in consequence of the first stump being thus diseased. A complete ganglion, or plexus of nerves, was found closely adhering to the removed portion of bone, having almost the appearance of cartilage. The os femoris was of an unusually small size, but the linea aspera larger than natural. (*See Lancet*, vol. i. p. 115; vol. iii. p. 192.) In the same hospital, Mr. Mayo also amputated at the hip, on account of the extreme sufferings caused by a diseased state of the nerves of a thigh stump. (*See NEUROMA.*) For some observations on the changes which occur in stumps after cicatrization, see STUMPS.

OF PARTICULAR AMPUTATIONS.

UPPER EXTREMITY.

AMPUTATION OF THE FINGERS.

Amputation of the fingers, or parts of them, is performed with one, or with two flaps, or with a circular or an oval incision, and is frequently required, either primarily or secondarily, on account of various accidents and diseases, as comminuted fracture, onychia maligna, necrosis, &c. The operation is most conveniently performed in the articulations, though exceptions sometimes occur in which it may be done elsewhere, and the phalanx divided with the cutting pliers. Thus it occasionally happens that either the distal or the middle phalanx is torn off, and the end of the proximate phalanx exposed: here it will often suffice to take away the denuded portion of it with the cutting pliers, and save a proper flap for covering the end of the remaining part. It is sometimes desirable to save as much as possible of the proximal phalanx, when amputation is rendered necessary by disease of the middle articulation, or of the distal extremity of

the bone. In such cases, after saving the requisite skin in the same way as recommended below for amputation in the articulations, the bone is divided either with a small saw or the cutting pliers.

Amputation of the Distal and Middle Phalanges.—The phalangeal articulations are but loosely supported in front by the anterior ligament, and behind by the extensor tendon: at the sides, however, they are much more closely held together by the lateral ligaments. Consequently, it is these which must be divided in order to open the joint freely. The line of the articular interval is nearly transverse. Between the first and second phalanx, it is on a level with the palmar cutaneous furrow; but, in the articulation of the second with the third phalanx, it is from half a line to a line below the palmar furrow. (See *J. F. Malgaigne, Manuel, &c.* p. 275.) In either of these joints the operation may be done, either with a single flap, taken from the palmar surface of the finger, or with two flaps, one formed from the palmar, and the other from the dorsal surface of the finger.

Amputation by the single palmar flap is performed, according to Lisfranc, in the following manner. The surgeon, taking hold of the finger and placing it in the bent position, makes a semicircular incision across the joint on the dorsal surface, half a line in front of the angle produced by flexion, cutting through the skin and opening the capsule by the same stroke; he then proceeds to divide the lateral ligaments, one after the other; and the knife being conveyed through the articulation, the operation is completed by the formation of the palmar flap, which is to be long enough to cover the entire surface of the stump.

Another method, also ascribed to Lisfranc, consists in attacking the joint on its palmar side. All the fingers, except that which is about to be amputated, are bent and held out of the way by an assistant. The point of a narrow straight bistoury is introduced from half a line to a line beyond the palmar cutaneous wrinkle, if we are amputating the distal phalanx, and exactly at the base of this wrinkle if we are removing the middle phalanx. The knife is to pass through the finger from one side to the other, and close to the anterior surface of the bone, along which it should be carried to the extent of rather more than half an inch, and then brought out, so as to complete a semilunar flap. The knife is then carried again to the base of the flap to divide the anterior ligament. In this operation the lateral ligaments scarcely require a separate division, for the same stroke of the knife which cuts the anterior ligament usually cuts them also, making room for the knife to pass through the articulation, and to divide the textures on the dorsal aspect, without forming any posterior flap. By this method, a more regular and better nourished flap is produced, and the operation is more sure of being effected with precision; but the extensor tendon is apt to remain too long, in which event its projecting end should be cut off with scissors. (*Malgaigne, Méd. Opér.* ed. 5, p. 277.)

[If two flaps are to be made, that from the palmar surface may be cut by transfixion, in the manner described in the last operation, only it may, of course, be considerably shorter than is there recommended; while that on the dorsum will be more conveniently made, not by transfixion, but by incision from without inwards, a few touches with the point of the knife enabling the surgeon

to reflect it upwards to the level of the joint. Both flaps should be made before opening the articulation.]

The *circular method* of amputating a finger is the oldest. The finger is put in an extended posture; a circular incision is made three or four lines beyond the articular interspace, the situation of which is denoted by the position of the palmar cutaneous furrow. The skin is dissected up as far as necessary, and the joint opened either in front or behind, as in the flap operation already described. Or, if the disease or injury will admit of it, the integuments may be drawn up before the circular cut is made, and thus little or no dissection of them from the subjacent parts will be necessary.

[A single flap from the dorsal surface may be thus formed. A semilunar incision should be made so as to form a flap about three quarters of an inch in length, the angles of which should be placed on each side of the articulation opposite to the commencement of the palmar furrow. This flap is to be dissected up to the joint, which is next opened from its dorsal surface by division of the lateral ligaments and extensor tendon. The operation is completed by causing the knife to cut its way out straight through the remaining tissues, situated on the palmar surface. This latter operation is only applicable to the articulation between the first and second phalanx. In the joint between the second and third, the proximity of the nail will prevent a flap being formed of sufficient size.]

In general, after amputation of the distal and middle phalanges, no ligature is required; the bleeding ceases as soon as the wound is brought together, which should be effected by means of one or two sutures and narrow strips of adhesive plaster.

The operation by the single palmar flap, or by flaps cut partly from the palmar and partly from the dorsal surface, are those most commonly recommended and practised. The circular incision has fallen almost entirely into disuse. The single flap from the dorsal surface is unnoticed by many writers; it has been mentioned, however, by Lisfranc, Delpech, Velpeau and others, and more recently by Mr. Skey. (*Op. Surg.* p. 349.) It is applicable to those cases where the palmar surface of the finger has been injured, but it possesses also the advantage that the flap is composed of the skin of the knuckle, which falls conveniently, of its own accord, over the end of the phalanx; and that the position of the cicatrix renders the loss of the finger less evident than when the flap has been cut from the palmar side. What is gained in appearance, however, is, perhaps, lost in utility; for the cicatrix though more out of sight, is more exposed to pressure from substances held in the hand.]

AMPUTATION AT THE METACARPO-PHALANGEAL ARTICULATIONS.

Each of these joints is of the enarthrodial kind, and furnished only with loose ligaments. The articular prominence, seen when the phalanx is bent, is formed by the head of the metacarpal bone. The joint is from three quarters of an inch to an inch above the digital commissure. The operation may be performed by lateral flaps, or by an oval incision.

1st Method, by Lateral Flaps.—The hand being placed in the prone position, and the other fingers held apart from the one about to be removed, the phalanx is to be bent, as Lisfranc directs, to an

angle of 45° , and an incision begun over the head of the metacarpal bone, about a quarter of an inch behind the articulation, and extended obliquely down the side of the finger, as far as the digital commissure, care being taken to divide as completely as possible the extensor tendon. The incision is then carried round to the palmar surface and continued backward, so as to terminate opposite the articulation, thus completing the first flap, which is to be reflected. The knife is now pushed into the exposed side of the articulation, the ligaments cut, and the operation finished by the formation of the opposite flap, which is cut from within outwards and ends like the first at the digital commissure.

When this operation is done on the index finger, the outer flap should be the larger; when on the little finger, the inner flap should have the greater size. (*Malgaigne, Manuel, &c.* ed. 5, p. 279.)

The following is Mr. Liston's description of this method:—The operator seats himself before the patient; grasps the finger so as to manage its movements with the left hand; and holding the knife perpendicularly, with its point upwards, lays it over the knuckle, and carries it obliquely upwards, so as to open that side of the articulation. He then pushes the finger towards the opposite side, and with the point of the knife completes the loosening of the articulation, which should never be done with the blade, as it would cross-cut and mangle the skin. After the separation of the base of the phalanx with the point, the blade is passed behind; and, being carried downwards and outwards, it forms a flap similar to the first. They are retained in contact by bringing the neighbouring fingers towards one another. In general, this will also stop the bleeding, but sometimes one or both digital arteries will require ligature. (See *Liston's Elements*, part iii. p. 375.)

[It will be found preferable to make both these flaps by incision from without inwards, and to complete both before opening the joint; in this way it is easier to make them correspond accurately than by the former methods.]

2nd Method, by Oval Incision.—The incision commences in the same way as in the first operation, and like it passes obliquely downwards as far as the digital commissure; but now, instead of being continued backward into the palm, it is carried transversely across the under surface of the finger, following exactly the cutaneous fissure which separates the finger from the hand. It is now made to pass obliquely upwards again on the opposite side of the finger, to join the original incision a little in front of the point where it commenced. The skin is held aside by an assistant, while the surgeon opens the joint on its dorsal surface, and then divides the lateral and afterwards the anterior ligaments to complete the disarticulation. This operation is not effected quite so rapidly as the former, but the wound made is a little less extensive, and does not encroach at all upon the palmar surface of the hand.

Dupuytren found that, when the ring or middle finger had been removed, without taking away the head of the corresponding metacarpal bone, the adjoining fingers remained widely separated at their base, but obliquely approximated to one another at their extremities, so as to produce a considerable deformity, and an imperfection in their functions; he used, therefore, not to be content with amputating the phalanges, but made it a rule to apply a re-

tractor, and saw off the head of the metacarpal bone. (See *Legons Orales, &c.* t. iv. p. 309.) Sir Astley Cooper has advocated the same practice, which is most readily accomplished with a pair of cutting pliers. Mr. Fergusson also strongly recommends the removal of about an inch of the metacarpal bone, as greatly lessening the deformity and not tending materially to diminish the strength of the hand. He advocates the extension of the same principle to the fore and little fingers. (See *Practical Surgery*, p. 216.) The portion of the metacarpal bone may either be removed together with the phalanges, or separately after these have been taken away, at the choice of the operator. The extension of disease to one of the metacarpo-phalangeal articulations may also be another reason for taking away more or less of the metacarpal bone along with the finger. If merely the distal end of the bone is affected, either of the above mentioned plans of operation will suffice, only the incisions should commence a little further back than is there laid down. And even when a considerable portion of the metacarpal bone is to be taken away, an extension of the incision backwards on the dorsal surface will be found sufficient without interfering further with the palm of the hand. "With this view the knife is entered over the dorsal centre of the bone, above the diseased part, and carried straight downwards till near the articulation, when it is made to diverge for the formation of lateral flaps. The integuments in the track of the wound are then dissected backwards, so as to expose the bone completely, and the bistoury is passed round it throughout its whole extent, the edge being kept close to it. Then the bone is clipped at the proper point by the cutting pliers; or the section of the bone may be performed before the separation of the soft parts from its under surface, as by raising the cut end this part of the operation may be facilitated." (See *Liston's Elements*, part iii. p. 377.)

[Two, three, or, perhaps, all four fingers may require removal at their metacarpal articulations.—When all four are to be taken away, a transverse incision, slightly convex forwards, should be made completely across the dorsum of the hand, from one end to the other, a quarter of an inch in front of the metacarpo-phalangeal joints. Disarticulation of these joints, one after the other, is now to be effected, when the knife may be made to cut a flap from the palm, which should extend forwards quite to the digital commissure. Care must be taken to leave the flap as large as possible at each side, otherwise there will not be sufficient covering for the heads of the second and fifth metacarpal bones. The elliptical incision, recommended by M. Soupart, seems well adapted to obviate the inconvenience just alluded to. He makes the dorsal incision convex upwards, its middle part reaching as high as the level of the articulations to be opened, and its extremities terminating at each side, at the commencement of the digito-palmar furrow. The hand being supinated, he makes a palmar incision, which follows exactly the digito-palmar fold, and joins the extremities of the one first made. The palmar flap is then dissected up, and the flexor tendons divided, after which, the hand being again placed in the prone position, the extensor tendons and lateral ligaments may be cut through, one after the other, and the joints disarticulated. (See *Malgaigne, op. cit.* p. 281.)]

[AMPUTATION OF THE PHALANGES OF THE THUMB.]

[*Amputation of the last phalanx* will not need a special description.

In amputation of both phalanges from the metacarpal bone, it should be remembered that here the head of the metacarpal bone is of a somewhat square shape, and broader than in the fingers. It will require, therefore, a larger covering to be left for it. This amputation may be done by lateral flaps, or by the oval incision, as in the fingers; but, perhaps, the best operation is that by an *elliptical incision*, as recommended by M. Malgaigne. He makes a dorsal incision convex *upwards*, the middle part of which passes a little above the level of the articular interspace, while its extremities terminate at each side at the commencement of the palmar cutaneous fold. The thumb being now forcibly extended, he makes on the palmar aspect a second incision convex *downwards*, which, joining at each side the extremities of the first, descends by its middle part as low as midway between the cutaneous fold, above referred to, and the fold which corresponds to the interphalangeal articulation. (Op. cit. p. 282.) The result is a palmar flap which, when it is applied over the end of the bone, has a convex edge, corresponding exactly with the concavity of the dorsal portion of the incision. M. Malgaigne prefers this mode of proceeding because it leaves the cicatrix well out of the way of injury from hard substances held in the hand. He removes at the same time the two sesamoid bones; but the reason for so doing, unless they happen to be implicated in the disease or injury which necessitates the operation, is not sufficiently apparent. If the anterior extremity of the metacarpal bone were diseased or injured, it might be removed with the cutting pliers; but if sound, it should always be allowed to remain.]

AMPUTATION OF THE THUMB AT THE ARTICULATION BETWEEN THE METACARPAL BONE AND THE OS TRAPEZIUM.

The metacarpal bone is almost subcutaneous at its posterior and external aspect, but covered by a thick mass of muscle on the side towards the palm. The articulation will be found about an inch below the styloid process of the radius; its direction is oblique, corresponding to a line, which, if carried far enough, would cross the root of the little finger. It has a loose capsule, which may be opened with great facility from its posterior and external surface. Upon this surface lie the tendons of the two first extensors of the thumb. The radial artery runs over its ulnar side on its way to the palm to form the deep palmar arch. The place of the joint is readily determined by passing the finger along the dorsal aspect or the sides of the metacarpal bone, from before backwards, for it is situated immediately behind the first bony tubercle. (See *Velpeau*, op. cit. p. 390.)

1st Method, by External Flap.—While the thumb is held in the position of abduction, the knife is applied to the middle of the commissure; an incision is made at once down to the carpus, dividing all the soft parts between the metacarpal bones of the thumb and forefinger, and terminating against the ulnar side of the articulation. This is to be opened by cutting outwards, the fibrous textures being divided rather with the point than with

the blade, so as not to mangle the skin; the thumb may now be dislocated, and a flap formed from behind forwards, by carrying the knife close to the outer side of the bone as far as a few lines beyond the metacarpo-phalangeal joint. If the radial artery has been wounded, it will require a ligature; but if not, bringing the flap accurately over the wound will most probably stop the bleeding. The edges should be maintained in apposition by two or three sutures and adhesive plaster, and contact of the surface of the flap with the parts beneath should also be secured by a compress and bandage. The operative procedure may be reversed as follows:—An assistant takes hold of the thumb, while the surgeon takes as much of the soft parts as possible with the fingers of his left hand, and draws them outwards. The latter then transfixes them with a straight narrow knife from behind forwards, or towards the palm, directing the blade close to the radial side of the articulation. A flap is then formed; and while this is held up by the assistant, the surgeon takes hold of the thumb, cuts through the joint from without inwards, luxates the bone, and with the knife cuts through the middle of the commissure. This method leads to the same result as the former, but, being more difficult, ought not to be preferred.

2nd, or Oval Method.—The incision is commenced upon the os trapezium, a little above the articulation, and is carried on the back of the thumb downwards, and to the ulnar side as far as the digital commissure; it should now pass round to the palmar surface of the thumb, and ascend obliquely on the radial side of the bone towards the original incision, which it should join about half an inch in front of its commencement. The point of the knife is next introduced into the articulation, which is cut through from its dorsal towards its palmar boundary. All that now remains to be done is to detach the bone from any fibres which may yet adhere to it, by carrying the knife in front of it from behind forwards. The wound, when brought together, represents a straight line, and is much less extensive than by the first method, which leaves a cicatrix on both aspects of the hand.

3rd Method.—*Velpeau* has frequently amputated the thumb in the following manner:—An incision is made along the back of the thumb from the styloid process of the radius to the commissure of the thumb and forefinger. This divides the integuments, the tendon of the long extensor, and a portion of the first interosseous muscle, so as to expose the joint. While an assistant holds aside the edges of the wound, the surgeon opens the capsule and dislocates the bone, which is then removed, care being taken to preserve as much of the flesh on the palmar side as will be required to close the wound immediately. Thus the palm of the hand is not at all wounded. (Op. cit. p. 392.)

AMPUTATION OF THE LITTLE FINGER TOGETHER WITH THE WHOLE OF ITS METACARPAL BONE.

[The articulation of the fifth metacarpal bone with the os unciniforme is situated nearly an inch and a half below the styloid process of the ulna. Its direction is oblique, corresponding to a line, which, if prolonged, would cross the centre of the metacarpal bone of the forefinger. Amputation may be performed here, as in the thumb, either by a flap or by an oval incision.

1st Method, recommended by Lisfranc, by a flap from the ulnar side.—The soft parts are to be drawn towards this side and transfixed opposite the articulation; the knife is to be carried forwards, being kept as close as possible to the bone, as far as about half an inch beyond the metacarpo-phalangeal joint. The flap thus made is held back, and the joint opened; the bone is then separated from the soft parts, and its detachment completed by division of the commissure.

2nd Method, by Oval Incision.—This is done on the same principle as in the thumb. A straight incision is commenced a little behind the articulation, and is carried forwards on the dorsal surface of the metacarpal bone as far as its centre; from it two diverging incisions should pass so as to form a sort of loop round the root of the little finger. The edges of the wound being held apart, the bone may then be disarticulated and separated from the soft structures still adhering to it.]

[AMPUTATION OF THE FIRST, SECOND, OR THIRD FINGERS AT THEIR CARPAL ARTICULATIONS.]

[It is not often that removal of one only of these fingers with its metacarpal bone will be required; but, if necessary, it will be most conveniently effected by a straight incision along the back of the metacarpal bone, forming a loop round the root of the finger, as recommended in the last case. This will admit of disarticulation and separation of the bone, without interfering in any way with the palm of the hand. The proceeding will be attended with very considerable difficulty from the closeness of the joints and the proximity of the other metacarpal bones on each side; it will, therefore, be essential that the operator should have an exact knowledge of the position of the joints and of the direction of the articular surfaces. Care should be taken not to wound the deep palmar arch when the knife is being applied to the palmar aspect of the bone.]

[AMPUTATION OF ALL THE FINGERS AT THE CARPAL ARTICULATIONS.]

[Modern surgeons never amputate the whole of the hand when there is a chance of saving any portion of it. A single finger should, if possible, be preserved; and if the thumb and one finger can be retained, a very useful member, comparatively speaking, will be the result. On this principle it has even been thought desirable, in cases requiring it, to remove all four fingers with their metacarpal bones, leaving only the thumb. In the latter case, the hand being prone, a transverse incision should be made upon its dorsal aspect, half an inch in front of the carpo-metacarpal joints. This incision should commence over the metacarpal bone of the forefinger, and, after passing across the hand, should be carried round its ulnar border, and made to traverse its palmar surface at the same level. There remain to be divided the structures between the thumb and forefinger, which may be done by passing the knife through them from behind forwards. The skin being drawn up by an assistant, the metacarpal bones may be disarticulated one by one, commencing from the ulnar side.]

AMPUTATION AT THE WRIST OR RADIO-CARPAL ARTICULATION.

The hand should be amputated at the joint of

the wrist, whenever the disease does not extend too high, and a sufficient covering can be preserved either from the integuments of the back of the hand, or from those of the palm. Amputation may also be done here by the circular incision, or by anterior and posterior flaps as recommended by Lisfranc. The circumstances of the case will often determine the choice; but whenever it is practicable the circular incision should be preferred, as it will be found to provide a better covering for the projecting styloid processes.

The scaphoid, semilunar, and cuneiform bones form a convexity, which is almost entirely received in the concavity of the radius, the ulna having no connection with this joint, except through the intervention of the triangular ligament, and to the extent of about four lines. The styloid processes of the radius and ulna can be readily felt, and they overlap the articulation on either side, so that to enter the joint the knife should be directed obliquely upwards beneath them. In this way the articulation will be arrived at with greater certainty than from its dorsal surface, for in attempting to enter it from the latter direction the surgeon might erroneously carry his knife into the medio-carpal articulation, over the head of the os magnum, instead of into the wrist joint itself.

The projection of the pisiform bone beyond the level of the palmar surfaces of the radius and ulna, must be remembered in the operation.

Amputation by the circular method is performed as follows:—An assistant draws up the integuments, and the surgeon, holding in his left hand the part he is about to remove, makes an incision all round the wrist, about an inch below the styloid processes. The skin may now be easily retracted nearly as high as the joint; a second incision, made so as to leave the pisiform and cuneiform bones just beyond it, divides all the tendons on a level with the retracted skin. The joint is then to be cut into on one side or the other, under the guidance of the corresponding styloid process, and the knife directed through the articulation in a line answering to the posterior convexity of the scaphoid, lunar, and cuneiform bones. The radial and ulnar arteries are now to be tied, but the interosseous here seldom requires a ligature. The wound is to be closed with the line of it in the transverse direction.

[*Flap amputations at the wrist* should be performed by cutting from without inwards; transfixion of the soft parts being difficult anteriorly, in consequence of the prominences of bone in the neighbourhood of the joint; and next to impossible posteriorly, on account of the convexity of the posterior surface of the carpus. The incisions should commence opposite the styloid processes, and two semilunar flaps should be formed rather more than an inch in length, from the integuments on the anterior and posterior surfaces of the wrist. These should be dissected up to the requisite extent and the tendons divided, after which the disarticulation may be completed in the same way as in the circular operation. Or the dorsal flap may be first formed and the joint then opened on its posterior aspect by division of the posterior and lateral ligaments, after which the knife can be carried through the joint, to complete the operation by the formation of the second flap from the palm. The latter part of this proceeding is, however, rendered difficult by the projection of the

pisiform bone; and care must be taken to carry the knife over it, so as not to include it in the flap. In forming the flaps, care must be taken to leave enough integument on each side, otherwise, the styloid processes will be likely to protrude at the angles of the wound. M. A. Guérin recommends a single flap large enough to cover the ends of the bones to be made from the palmar surface, the angles of which are to be united across the dorsum of the wrist by an incision slightly convex upwards, this he thinks preferable to the circular method, as it will leave a cicatrix more out of the way of irritation from pressure. (*Elém. de Chir. Opér.* 1855, p. 122.) This, it will be observed, is another application of M. Soupart's elliptical incision.]

AMPUTATION OF THE FORE-ARM.

This operation may be performed at any point between the elbow and the wrist; but it is now always considered desirable to retain as much of the limb as possible, notwithstanding the objections entertained by Larrey and some other surgeons to amputation through the tendinous structures in the lower third of the fore-arm. The usefulness of the member will be increased if the amputation can be performed below the attachment of the supinator radii brevis, and pronator radii teres, because the movements of pronation and supination will be thereby preserved. (*Skey, Op. Surg.* p. 339.)

Circular Method.—A tourniquet is to be applied over the brachial artery, or if preferred the vessel may be compressed by the fingers of an assistant. A second assistant should steady the limb and retract the skin upwards. A circular incision is now to be made down to the fascia, and as much skin is to be detached, reflected, and saved as will be required to cover the ends of the bones. The muscles should next be cut through down to the bones on a level with the reflected skin, and a narrow double-edged knife should be passed between and around them to divide the interosseous membrane and completely isolate the bones from any of the deep fibres which may remain attached to them. This having been carefully accomplished, the soft parts are to be protected from the saw by a linen retractor. If the operation is in the upper third of the fore-arm, it may, perhaps, be sufficient, in consequence of the greater abundance of soft parts, to retract the skin only, without reflecting it back; and in this situation, after the first division of the muscles in the manner above recommended; a second incision may be made at a somewhat higher level through the deeper fibres which are adherent to the bone. It is usually recommended that both bones should be sawn together; but that the division of the radius should be first completed, as the ulna, in consequence of its connection with the humerus, is better adapted to bear the weight of the saw. The ulnar, radial, and two interosseous arteries, will usually require ligatures.

Amputation by Flaps.—Graefe removed the fore-arm by making a flap from the flesh in front of the limb, and then extending the wound quite round the member. (*Normen für die Abölsung grösserer Gliedm.* p. 138, &c. 4to. Berlin, 1812.) Mr. Guthrie made two flaps, one in front, the other on the back of the fore-arm: but above the middle of this part of the limb he preferred the circular incision. (*On Gunshot Wounds*, p. 373, 374.)

Dr. Hennen also expressed his approbation of amputating the fore-arm, so as to make two semilunar flaps (*Principles of Military Surgery*, p. 265. ed. 2), which is the method recommended and practised by Klein (*Practische Ansichten bedeutendsten Operationen*, heft i. p. 45); and Lisfranc also operated in this way at the lower third of the fore-arm. Amputation with *one flap* should be confined to those cases where the soft parts are destroyed to a greater extent on one side of the limb than on the other.

[In the amputation with *two flaps* the arm should be held in the supine position and a flap should be formed of the requisite length from the anterior surface by transfixion; the limb should then be pronated so as to bring the dorsal surface into view, and a posterior flap formed of a semilunar shape by incision from without inwards, or from the skin towards the bones. Both these flaps should be reflected up by an assistant, and the operation then completed in the same way as in the circular method. In the lower half of the fore-arm the tendons are liable to be drawn out over the edge of the knife and to be left longer than the integument. When this is the case, they must be cut off with the scissors to the requisite level. This is an application to the fore-arm of the mode of amputation recommended for the thigh by Mr. Luke. It will be found more convenient to proceed in this way than to form both flaps by transfixion, on account of the proximity of the bones to the posterior surface of the limb.]

AMPUTATION AT THE ELBOW-JOINT.

Dupuytren, convinced of the correctness of the principle, that as much as possible of the upper extremity should always be saved, revived the practise of amputating at the elbow, whenever the state of the joint and of the soft parts admitted of such operation. This operation was performed by Dupuytren in ten or twelve examples with great success, and the method is also highly commended by Mr. Liston. (*See Elem. of Surgery*, part iii. p. 381.) Notwithstanding these authorities, however, it is not much in favour at the present time, and is rarely practised by English surgeons.

[It must be borne in mind that the joint is placed at some distance below the condyles of the humerus, and that its direction is oblique, extending lower down on the inner than on the outer surface of the limb. The articulation will be found nearly an inch below the prominence of the internal, and about half an inch below that of the external condyle.]

The circular method is recommended by M. Velpeau and also by Dupuytren when there is not a sufficiency of soft parts for an anterior flap. The incision should be made three fingers' breadth below the level of the joint and should extend through the integuments only; these should be drawn upwards, or reflected if necessary, as high as the articulation; the muscles should then be cut through, the joint opened and the disarticulation completed. The brachial artery will be divided before its bifurcation, and will be the only vessel requiring a ligature.

Anterior Flap.—The fore-arm being slightly bent, the soft parts in front should be transfixed opposite the joint, and a flap should be cut of sufficient extent to form an ample covering for the end of the

bone; the flap should be of large size, in consequence of the retractibility of the skin opposite the flexure of the elbow. A transverse incision across the posterior half of the limb should unite the angles of this flap. The joint is then opened, and the ligaments and remaining tendons divided. The knife will be found to enter the joint more readily on the outer side, between the external condyle and the head of the radius, than elsewhere. The olecranon will be firmly fixed by the attachment of the triceps; this tendon may be divided, or the bone may be sawn through. Dupuytren practised both methods, but without any material difference in the result; most surgeons would probably prefer to remove the whole of the bone. The operation last described was that practised by Dupuytren, excepting that he transfixed the limb at the level of the condyles, which is nearly an inch higher than is necessary, and tends to leave them uncovered afterwards. The ulnar, and radial, and probably also the interosseous arteries will require to be ligatured. M. A. Guérin recommends an *external flap*, which may be cut by transfixion of the limb on the outside of the neck of the radius; the angles of the flap to be united by an incision convex downwards, round the inner half of the circumference of the fore-arm. This would obviate all risk of protrusion of the condyles; and M. Guérin considers that it also provides a better covering for the articular surfaces. (See *Elém. de Chir. Opér.* p. 130.)

AMPUTATION OF THE ARM.

The arm, like the thigh, contains only one bone, round which the muscles are arranged. The deep muscles are attached to the humerus, while the superficial extend along the limb without being adherent to the bone. The first consist of the brachialis anticus and the two short heads of the triceps: the second of the biceps and long head of the triceps. The arm may be amputated by the circular incision or by antero-posterior or lateral flaps, at the option of the surgeon, or as the nature of the disease or injury may indicate.

Circular Operation.—The patient being placed in the recumbent position, with the shoulders raised, the arm should be separated from the side, if the disease will allow it, so as to form a right angle with the trunk of the body. A tourniquet is to be placed on the brachial artery as high as possible; or, if it be preferred, an assistant, standing behind the shoulder, makes pressure on the axillary artery with his four fingers. The skin and muscles, which are about to be divided, are to be drawn up and made tense. The surgeon, usually standing on the outside of the limb, makes a circular incision through the integument and fascia down to the muscles. There will be no necessity to dissect the skin back from the subjacent parts, unless it has become thickened and adherent from disease; under ordinary circumstances, its effectual retraction by an assistant will be found sufficient. When it has been drawn up as far as possible, the knife may be carried through all the remaining soft parts down to the bone. The superficial muscles will contract and recede upwards, but the deeper fibres are prevented doing so by their adhesion to the bone, and should therefore be divided about an inch higher up by a third circular sweep of the knife. The retractor is to be applied, the bone sawn through with the usual precautions, and the

bleeding stopped in the ordinary way. The wound is then to be closed so as to form a transverse line; the dressings are to be applied, and the patient put to bed, with the wound a little elevated from the surface of the bedding. Dupuytren recommends a circular incision to be made at once through the skin and biceps, and loose part of the triceps. The edge of the knife is then applied close to the margin of the retracted muscular fibres, and the brachialis, the rest of the triceps, &c., divided by a circular incision down to the bone, directed sometimes perpendicularly, sometimes obliquely. Lastly, the muscular fibres, closely adherent to the part of the bone above the incision, are detached from it some way upwards with a scalpel, so that the saw can be applied higher up than would otherwise be practicable. This plan combines all the quickness of a flap amputation with another advantage ascribed to the latter, namely, that of no risk of a subsequent protrusion of the bone.

Flap Operation.—The arm may be amputated with two semilunar flaps, the one anterior the other posterior. The surgeon with his left hand raises the soft parts from the front of the bone, transfixes the limb with a sharp pointed knife, and cuts an anterior flap about three inches in length; then passing the knife behind the bone, he makes a similar flap from the posterior surface. These being held back by an assistant, the muscular fibres are divided all round and the saw used. Three strokes of the knife, as M. Velpeau observes, one for each flap, and another for the division of the muscular fibres adherent to the bone, and then the use of the saw, bring the operation to a conclusion. Yet it is contended, that flap amputations of the arm are followed by more inflammation of the stump than circular ones, for which the round shape of the limb, and the moderate size of its single bone, seem admirably to adapt it. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 425.) Langenbeck, instead of making the flaps in the preceding way, by transfixion, forms two lateral ones by cutting in the opposite direction, or from below obliquely upwards, and from the skin towards the bone.

Amputation in the Upper Third of the Arm.—If the disease should require the arm to be taken off at its upper part, there would be no room for the application of the tourniquet. Here, instead of putting a compress in the axilla, and having it held firmly upon the artery by a bystander, as advised by Sabatier, it is more eligible to make pressure on the artery as it passes over the first rib; of which method I shall speak in treating of amputation at the shoulder-joint. With a straight bistoury, the surgeon is now to make a transverse incision down to the bone, a little above the lower extremity of the deltoid muscle. Two other longitudinal incisions, made along the front and back edge of this muscle, now form a flap, which must be detached, and reflected. Lastly, the rest of the soft parts of the limb are to be divided by a circular cut, made on a level with the base of the flap, and the operation finished like a common amputation. (*Sabatier, Méd. Opér.* t. iii. p. 375, &c. ed. 2.) [There is no advantage in the square shape of the flap recommended by Sabatier, it would therefore be better to employ transfixion, and to make it of the usual semicircular form.]

When the arm is injured very high up, Baron Larrey prefers amputation at the shoulder-joint to

preserving a short stump, containing the upper end of the humerus : for, says he, if this bone cannot be divided at least on a level with the tendinous insertion of the deltoid, the stump is retracted towards the armpit by the pectoralis major and latissimus dorsi; the ligatures on the vessels irritate the brachial plexus of nerves; great pain, and nervous twitchings, often ending in tetanus, are produced; the stump continues swelled; and, in the end, the humerus is fixed by ankylosis to the shoulder, so that this portion of the arm remains altogether useless, and renders the patient liable to accidents. "I have seen (says Larrey) many officers and soldiers, who, on these accounts, were sorry that they had not undergone amputation at the shoulder." (*Mém. de Chir. Mil.* t. iii. p. 53, 400.)

Mr. Guthrie also states, that when amputation by the circular incision is attempted at the insertion of the pectoralis major, the bone will generally protrude after a few dressings. However, he entirely dissents from Larrey, respecting the necessity of taking off the limb at the shoulder, and prefers doing it from half an inch to an inch and a half below the tuberosities of the humerus, as the state of the injury may require. He recommends amputation here by an oval incision, similar to that presently recommended, for removal of the limb at the shoulder-joint, excepting that it should commence about two inches lower down. Without detaching the skin from the muscles, these are cut through; the soft parts are held out of the way of the saw; the bone is sawn; the vessels secured; and the flaps brought together, so as to form a line from the acromion downwards. (*Gunshot Wounds*, p. 337, &c.) I am decidedly of opinion that, in the description of cases referred to, either this method or Sabatier's operation should be preferred to the removal of the whole limb at the shoulder-joint.

[The only advantage possessed by the oval over the circular incision in this situation is that it permits the bone to be exposed at a higher level. In the circular method, it is often difficult, on account of the proximity to the trunk, to retract or reflect the skin sufficiently; the bone is therefore not sawn through high enough up, and protrusion takes place in consequence.]

AMPUTATION AT THE SHOULDER-JOINT.

[Amputation at the shoulder-joint will be necessary in cases of severe injury to the arm from gunshot wounds, in some cases of compound fracture extending into the joint, laceration of the arm by machinery, mortification, &c., also, occasionally, in consequence of extensive disease of the humerus, and in some cases of tumors, malignant or otherwise, involving the bone or the soft parts of the arm, and extending high up in the direction of the shoulder, so as to approach near to or implicate the joint.]

Amputation at the shoulder has been partly superseded of late years by a preferable operation, even in cases in which it would formerly have been deemed indispensable, such as considerable gun-shot fractures of the head of the humerus, a caries of the substance of this part, &c. Boucher, in 1753, proved that considerable wounds, extending into the shoulder-joint, might be successfully treated by extracting the fragments and splinters of bone. (*Mém. de l'Acad. de Chir.* t. ii. p. 287 et 461.) For further information on this subject, and for the selection of cases in which the practice may be fol-

lowed with advantage, see *Excision of Shoulder-joint*.

The head of the humerus represents nearly the half of a sphere, scarcely one-third of which is received by the glenoid cavity of the scapula, the rest being contained in the exceedingly loose capsule of this articulation. The articular surfaces are held together principally by the deltoid, supraspinatus and infra-spinatus, teres minor, and subscapularis muscles. The joint is also very much strengthened by the tendon of the long head of the biceps and by the coraco-humeral ligament. Above the articulation is a kind of osseo-fibrous arch, formed by the acromion, the coracoid process, and the ligament stretched between them. This arch projects more than an inch over the glenoid cavity, and descends further in the direction backwards than in that forwards. (See *J. F. Malgaigne, Manuel de Méd. Opér.* p. 294.) If we examine the anatomy of the shoulder, from above downwards, we first meet with the deltoid muscle, covered by the integuments, some fibres of the platysma, and a very thin fascia. Then we come to a loose cellular tissue, the tendons of the supraspinatus, infra-spinatus, subscapularis, and teres minor, the accessory ligament and fibrous capsule, and the tendon of the long head of the biceps. Lower down we arrive at the scapular portion of the triceps; and then the brachial plexus of nerves, the axillary vessels; and, under the skin, the pectoralis major, the latissimus dorsi, and the teres major. The apex of the acromion is very perceptible just above the cushion of the shoulder, and the coracoid process may be felt more towards the chest. Between these bony points is situated a triangular interval, useful to be recollected by the practical surgeon, bounded outwards and downwards by the head of the humerus; above by the clavicle and acromion, or rather by the coraco-acromial ligament; and inwardly by the coracoid process. This is the place where the joint may be at once cut into without any impediment from the bones; and it is on the knowledge of this fact that Lisfranc proposed one of his methods of amputating at the shoulder. When the posterior border of the axilla is reflected towards the scapula, as Velpeau observes, the knife may be made to pass below the acromion, into the superior and external part of the joint. In some persons the acromion is much more prominent than in others; and occasionally it is considerably depressed, so that its humeral aspect forms a deep concavity. In childhood it is cartilaginous; and Velpeau found it in two adult bodies separable by a very slight effort, as an epiphysis from the spine of the scapula. (*Velpeau, Nouv. Elém.* t. i. p. 428.) The course of the circumflex arteries and of the circumflex nerve; the origin and track of the tendon of the long head of the biceps, between the fibrous capsule and the synovial membrane into the bicipital groove of the humerus; the mode in which the capsule is attached to the humerus just beyond its anatomical neck; the very open angle formed by the junction of the head with the shaft of the bone; and the circular shape of its head, requiring an incision of corresponding figure for the prompt division of the fibrous capsule,—are all interesting points of surgical anatomy, without a due knowledge of which a surgeon cannot amputate at the shoulder with skill and judgment.

Whether the operation done by Laroque, in 1686, was truly an amputation at the shoulder-

joint, or merely the separation of a gangrenous limb by a natural process, and a little assistance of the surgeon, may admit of dispute. I believe that H. F. Le Dran performed the first operation of this kind of which the particulars are clearly recorded. It was in a case of caries and exostosis, reaching from the middle to the neck of the humerus. Le Dran began with rendering himself master of the bleeding, for which purpose he introduced a straight needle, and a strong ligature under the artery. This was passed from the front to the back part of the arm, as closely to the axilla and bone as possible. The ligature, then, including the vessels, the flesh surrounding them, and the skin covering them, was tightened over a compress. Le Dran, with a straight narrow knife, then made a transverse incision through the skin and deltoid muscle down to the joint, and through the ligament surrounding the head of the humerus. An assistant now raised the arm, and dislocated the head of the bone from the cavity of the scapula. This allowed the knife to be passed with ease between the bone and the flesh. Le Dran then carried the knife downward, keeping its edge always somewhat inclined towards the bone. In this manner he gradually cut through all the parts, as far as a little below the ligature. As there was a large flap, Le Dran made a second ligature with a curved needle, which ligature included a great deal of flesh, the redundant portion of which was cut off together with the first ligature, which had become useless. The cure was completed in about ten weeks. (*Obs. de Chir.* t. i. p. 315, Paris, 1731; and *Traité des Opér.* p. 365.) Le Dran (the son), who published this memorable case, does not state that the operation was a new one; and it appears from the *Recherches Critiques sur l'Origine, &c. de la Chirurgie en France*, and from La Faye's notes on Dionis, that it had been previously practised by Morand the father.

Garengot thought that the ligature might be applied by means of a curved needle, with sharp edges; and, in order to lessen the wound, he directs the incision to begin two or three finger-breadths below the acromion, across the deltoid muscle, so as to form one flap; then a lower one was made in the axilla; and after the second ligature had been applied, the two flaps were brought into contact. (*Traité des Opér. de Chir.* t. iii. p. 350; *Mém. de l'Acad. de Chir.* t. ii. p. 261.)

La Faye extended the improvements further. After placing the patient in a chair, and bringing the arm into a horizontal position, he made a transverse incision in the deltoid muscle down to the bone, four finger-breadths below the acromion. Two other incisions, one in front and the other behind, descended perpendicularly to this first, and made a large square flap which was detached, and turned up towards the top of the shoulder. The two heads of the biceps, the tendons of the supra-spinatus, infra-spinatus, teres minor and subscapularis, and the capsular ligament, were next divided. Now, when the assistant, who held the lower part of the limb, made the bone describe the motion of a lever, upward, the head of the bone was easily dislocated. La Faye next carried his incision downward, along the inner part of the arm, until he was able to feel the vessels, which he tied as near the axilla as possible. The separation of the limb was then completed, a finger's breadth below the ligature. The flap was then brought

down over the glenoid cavity, and the wound dressed. (See *Nouvelle Méthode pour faire l'Opération de l'Amputation dans l'Articulation du Bras avec l'Omoplate*, par M. La Faye, in *Mém. de l'Acad. de Chirurgie*, t. v. p. 195, ed. in 12mo.)

The advantages of La Faye's plan are obvious. As only one ligature was applied, the patient was saved a great deal of pain: the flap connected with the acromion was capable of covering the whole surface of the wound, and was more easily applied and kept on the stump than the lowermost of the two flaps which Garengot recommended; and the discharge found a ready outlet downwards. The amputation by external flap formed from the deltoid muscle is yet regarded as one of the most approved, where the state of the soft parts will admit of it.

In 1760, P. H. Dahl published at Gottingen a dissertation on amputation at the shoulder. In this tract a tourniquet was proposed, the pad of which was calculated to press upon the subclavian artery under the clavicle, and enabled the operator to dispense with tying the vessels in the first instance. Camper had observed, that if the scapula were pushed backward, and the axillary artery pressed with the finger between the clavicle, coracoid process, and great pectoral muscle, the pulse at the wrist might be instantly stopped.

Dahl's tourniquet was obviously constructed, in consequence of what Camper had observed. It is made of a curved elastic plate of steel, to the shortest end of which a pad is attached, capable of projecting further by means of a screw. The instrument embraces the shoulder from behind forward, while the pad presses on the hollow under the clavicle, between the margins of the deltoid and pectoral muscles. The long extremity of the steel plate, which descends behind the shoulder, is fixed to the body by a sort of belt. The pad is depressed until the pulsation of the axillary artery is stopped.

Further experience has proved, however, that this tourniquet may be dispensed with, and the flow of blood in the axillary artery commanded, by properly compressing this vessel with the end of a key covered with soft materials, or even with the fingers alone, as some operators prefer, at the place where the vessel emerges from between the scaleni muscles, above the middle part of the clavicle. Thus the artery is pressed between the pad or fingers and the first rib, across which it runs. In certain plans of operation hereafter to be described, all compression of the artery either above or below the clavicle, is dispensed with.

The principal methods of amputating at the shoulder-joint, may be comprised under four varieties; 1st, the operation with the *circular incision*; 2nd, with *one flap*; 3rd, with *two flaps*; 4th, by the *oval incision*; but it will be obvious that no mode of amputating at the shoulder can be exclusively employed in all the cases requiring the operation, because the soft parts around the joint are frequently destroyed, or very much injured, to a greater or lesser extent, so that the surgeon is obliged to save skin and muscles wherever he can find them.

Circular Method.—In 1774, Alanson amputated at the shoulder-joint, as follows:—The subclavian artery was compressed by the fingers of an assistant. An incision was made about a hand's breadth below the acromion, and carried through

the integuments all round the limb. The deltoid and posterior muscles were then obliquely divided up to the capsular ligament. The tendon of the biceps, and the capsular ligament upon the anterior and posterior part of the joint, were now cut through. One of the circumflex arteries, which bled a good deal, was next tied. The great pectoral muscle, the rest of the capsule, and all the other parts, except the vessels and nerves, were then divided; but previously to cutting the vessels, a temporary ligature was put round them. Thus the separation of the limb was completed. The mouths of the vessels were drawn out and tied, and the temporary ligature taken away. Lastly, the sides of the wound were brought together, so as to make a transverse line. Graefe, seeming not to recollect that amputation by the circular incision, directed obliquely upwards, had been practised by Alanson, and even by some surgeons spoken of by Garengot, mentions it as a new proposition. In one case, after operating in this manner, his patient was quite well in three weeks; and, with the particular sort of knife which he uses, and which is broadest towards its point, he pretends to be able to make the oblique incision through the muscles all round the limb with one sweep. He is careful to make pressure on the artery, both with Mohrenheim's compressor applied under the clavicle, and the fingers of an assistant above it. (See *Normen für die Abl. grösserer Gliedm.* p. 110, &c.) M. Cornuau and M. Velpeau have also suggested modifications of circular amputation at the shoulder. In the method of the former, the integuments, being drawn up by an assistant, are divided four inches below the acromion, and the muscles next cut through transversely by one stroke of the knife, from the coraco-brachialis to the tendon of the teres major. The muscles are then raised, the joint opened, the knife passed through it from above downwards, close to the neck of the humerus, and a second transverse incision made, which joins the extremities of the first, divides the artery, and leaves a circular wound. This would not be a disadvantageous method, were the soft parts all tolerably sound.

M. Velpeau informs us, that he has tried on the dead subject every variety of the circular method, and he believes that no other plan is more expeditious, or leaves a more regular wound, or one more disposed to union by the first intention. He prefers dissecting up, and reflecting the integuments for two inches, without meddling with the artery; and then cutting the muscles in M. Cornuau's way, as close as possible to the joint through which the knife is to be carried; and finally, the triceps divided, together with the artery, which is first to be taken hold of by an assistant. (See *Velpeau, Nouv. Elém.* t. i. p. 430.)

External Flap.—The formation of an external flap of square shape from the deltoid muscle, as recommended by La Faye, has already been described, and this was the plan which I adopted after the battle of Waterloo, excepting that I did not cut the brachial artery till I had made the last stroke of the knife, which separated the limb, and consequently I did not tie that vessel till the time when I had nothing but the hemorrhage to occupy my attention. The circumflex arteries I tied as soon as the external flap was made.

Richerand describes nearly the same plan as that advised by La Faye, and he seems to have

been one of the first to dispense with compression of the axillary artery, for instance, after making the deltoid flap, cutting the tendons, and dislocating the bone, he dissects down close to the inside of the humerus, so as to enable an intelligent assistant to put his thumb on the cut surface behind the artery, which, with the aid of the fingers, applied to the skin of the axilla, can then be grasped and compressed, so as to command the flow of blood through the vessel. The operator now, fearless of hemorrhage, completes the internal or inferior flap. (*Richerand, Nosographie Chir.* t. iv. p. 509—511, edit. 4.)

Baron Dupuytren made a semicircular flap from the deltoid muscle by transfixion. The arm being raised and held at a right angle with the trunk, Dupuytren stood at the inside of the limb, with one hand grasped and elevated the mass of the deltoid muscle, and plunged under it a two-edged knife, from before backward, on a level with the end of the acromion. Cutting in this way close to the head of the humerus, he continued the incision downward between this bone and the deltoid, and, at length bringing out the knife, completed the external or superior flap. The rest of the operation did not essentially differ from Richerand's, except that Dupuytren took hold of the lower flap himself, before dividing it, and compressed the artery, until he had cut through it and tied it.

Instead of transfixing, the surgeon may form a flap of this shape by incision from without inwards, after which the soft parts can be dissected from below upwards, towards the joint.

Anterior and Posterior Flaps.—Desault recommended the formation of two flaps, one of which was anterior, the other posterior. The axillary artery was compressed from above the clavicle, at its coming out from between the scaleni muscles, whilst the integuments and flesh of the upper and internal part of the arm were pushed away from the humerus. A knife was plunged between these and the other soft parts behind, to make the anterior flap. The arm being inclined backward and outward, the humeral artery was tied, the articulation opened, and the head of the bone dislocated. The knife was then carried downward and backward, so as to form the posterior flap, the incisions meeting in the axilla. (See *Sabatier, Méd. Opér.* t. iii. p. 393—399, ed. 2.)

Larrey, who had frequent opportunities of amputating at the shoulder-joint, aimed at the same object which Desault did; but, in his earlier operations, he was in the habit of beginning with the formation of the external or posterior flap, for the following reason: by proceeding in this way, the surgeon can tie the humeral artery more safely, because the ligature is applied after the operation is entirely finished, and consequently at a time when there is nothing to be attended to but the hemorrhage. Thus, the patient being placed on a stool, and well supported, the arm is to be raised from the side, and the axillary artery compressed from above the clavicle. The integuments and other soft parts of the upper and outer portion of the arm are then to be pushed away from the humerus, and the posterior flap formed. It is now very easy to cut the tendons of the infra-spinatus and teres minor, and open the outside of the joint. The limb is to be carried inward, and luxated backward. The tendons of the supra-spinatus and biceps are to be divided; and as soon as the

head of the bone is out of the glenoid cavity, the knife is to be carried along the internal part of the head and neck of the humerus, with its edge close to the bone. An anterior flap, equal to the posterior one, is to be formed, consisting of a portion of the deltoid, great pectoral, biceps, and coracobrachialis muscles, and including the brachial vessels and nerves. The artery is to be taken hold of with a pair of forceps, and tied. Any other vessels which require a ligature are also now to be secured. (See *Mém. de Chir. Militaire*, t. ii. p. 170.)

When Larrey published his campaign in Egypt, he had operated in this way on nineteen patients, thirteen of whom recovered. But, at a subsequent period, he and his colleagues had amputated at the shoulder in upwards of a hundred cases, more than ninety of which recovered. (*Mém. de Chir. Mil.* t. iv. p. 432, 8vo. Paris, 1817.)

In Dupuytren's second method, which he preferred, whenever the state of the soft parts admitted of it, he formed an anterior and a posterior flap. The arm being raised to a right angle with the trunk, the heel of the interosseous knife or catlin, is placed below and a little in front of the acromion. Thence the operator cuts with a firm hand, and by one stroke, all the soft parts at the back of the shoulder down to the posterior border of the axilla. The flap being raised, exposes the back of the articulation. The elbow is now carried to the front of the chest, so as to make the head of the humerus prominent, and the tendons and capsule are divided upon it. The bone having been disarticulated, the knife is carried round its head from behind forwards, is conveyed from above downwards along the anterior surface of the humerus, so as to form the second flap, the detachment of which is completed as soon as an assistant has taken hold of its base, and compressed the artery included in it between his finger and thumb. Unless the surgeon were an ambidexter, he should stand in front of the patient in operating on the left shoulder, and commence with the anterior flap. Dupuytren regarded this last method as particularly advantageous. The two flaps extend in the direction of the longest diameter of the wound, and can be brought together with exactness and facility. The ligatures, twisted into a single cord, and brought out downwards, form a kind of conductor for the purulent matter outward. The cicatrix resulting from the operation is linear, and promptly formed, with less risk of axillary abscesses than after the other method. (See *Leçons Orales de Clin. Chir.* t. iv. p. 326.) These observations are subject to the consideration, that, when the patient is put to bed after the removal of the arm at the shoulder, the most depending point of the wound may be in some degree regulated by the position in which he lies. If an anterior and posterior flap were formed, he should lie with his chest raised forwards; if a flap had been formed above, and the line of the wound were transverse, he should be placed with the shoulder less elevated.

Another plan of amputating at the shoulder has been proposed by Lisfranc. Supposing the left extremity is to be removed, the patient is placed on an elevated seat, one assistant pressing the artery against the first rib, whilst another draws the arm forwards; the operator, standing behind the patient with a long-bladed catlin, pierces the

integuments on the inner edge of the latissimus dorsi muscle, opposite the middle of the axilla, and pushes it obliquely upwards and forwards, till its point strikes against the under surface of the acromion; then, by raising the handle of the knife, its point is lowered, and protruded just in front of the clavicle at its junction with the acromion. By cutting downwards and outwards, he then forms a flap from the superior and posterior part of the arm, including the whole breadth of the deltoid muscle, and a part of the latissimus dorsi, dividing also the tendons inserted into the great tuberosity, and opening the capsule by the same stroke. This flap being held back by the assistant, the joint is cut through from behind forwards, and a corresponding flap is formed by cutting downwards and outwards, between the muscles and bone, on the inner side of the arm. When the operation is on the right side, the patient should be seated on a low chair, and the catlin thrust from above downwards, from the part just in front of the point where the clavicle is connected with the acromion, the surgeon raising his hand as the instrument proceeds downwards and backwards, until its point has come out at the inner edge of the latissimus dorsi, when the flap is to be made, and the operation finished as above directed. (See *Averill's Operative Surgery*, p. 135. Also *Lisfranc de St. Martin, et Champesme, Nouveau Procédé Opératoire pour l'amputation du bras dans son articulation scapulo-humérale*. Paris, 1815.) [This method is very rapid and brilliant when well performed, but it requires a practised hand and considerable dexterity to prevent the knife becoming fixed between the head of the humerus and the acromion. This embarrassment is all the more likely to occur if the acromion is prominent, and especially if it projects forwards over the shoulder more than usual, which is sometimes the case.]

Oval Incision.—Mr. Guthrie, who was one of the first to recommend this mode of operation, commences the first incision immediately below the acromion, and, with a gentle curve, extends it downwards and inwards, through the integuments only a little below the anterior fold of the armpit. The second incision outwards is made after the same manner; but is carried rather further down, so as to expose the long head of the triceps at the under edge of the deltoid. The third incision, commencing at the same spot as the first, but following the margin of the retracted skin, divides the deltoid on that side down to the bone, and exposes the insertion of the pectoralis major, which must be cut through. This flap is now to be raised, so as to expose the head of the bone. The fourth incision outwards divides the deltoid muscle down to the bone, when the posterior flap is to be well turned back, so as to bring into view the teres minor and infra-spinatus passing from the scapula to the great tuberosity of the humerus. The outer and inner flap being now raised, the head of the bone may be rolled a little outwards, the teres minor and infra-spinatus cut, and an opening made into the joint. The capsular ligament, supra-spinatus, and long head of the biceps are then divided. The inner side of the capsule is now cut through, together with the subscapularis muscle, as it approaches its insertion into the lesser tuberosity of the humerus. The long head of the triceps is next divided; and, lastly with one sweep of the knife, the rest of the soft parts are cut, together with the

axillary artery, veins, and nerve. (*On Gunshot Wounds*, p. 274—276.)

The plan adopted by Larrey in his latter operations, produces a result essentially similar to that just described. Larrey first makes a longitudinal incision from the acromion to about an inch below the neck of the humerus, down to the bone, so as to divide the fleshy part of the deltoid into two even parts. This cut, he says, facilitates and renders more exact the rest of the operation. From this wound, the incisions for the flaps are continued. Having made the foregoing incision, "I direct an assistant to draw up the skin of the arm towards the shoulder, and I form the anterior and posterior flaps by two oblique strokes of the knife made from within outwards and downwards, so as to cut through the tendons of the pectoralis major and latissimus dorsi. There is no risk of injuring the axillary vessels, as they are out of the reach of the point of the knife. The cellular connections of these two flaps are to be divided, and the flaps themselves raised by an assistant, who, at the same time, is to compress the two divided circumflex arteries. The whole joint is now exposed. By a third sweep of the knife, carried circularly over the head of the humerus, the capsule and tendons running near the articulation are cut; and the head of the bone being inclined a little outwards, the knife is to be carried along its posterior part, in order to finish the section of the tendinous and ligamentous attachments in that direction. The assistant now applies his forefingers over the brachial plexus, for the purpose of compressing the artery, and commanding the current of blood through it. Lastly, the edge of the knife is turned backwards, and the whole fasciculus of axillary vessels is cut through, on a level with the lower angles of the two flaps, and in front of the assistant's fingers. The patient does not lose a drop of blood; and ere the compression is remitted, the extremity of the axillary artery is readily seen, taken up with a pair of forceps, and tied. The circumflex arteries are next secured, which completes the operation." (*Mém. de Chir. Mil.* t. iv. p. 428. Paris, 1817.)

Larrey takes no measures in the first stage of the operation for commanding the flow of blood, as the assistant merely presses the axillary artery between his fingers just before it is divided.

Larrey affirms, that the above described way of operating is applicable to almost every case met with in military practice. First, because all gunshot wounds, generally, which mutilate the arm, so as to create the necessity for the operation, partly, or entirely destroy the centre of the deltoid, while there is always enough flesh left at the sides for making the two flaps. Secondly, because, in the very rare instances where the lateral parts of the shoulder are destroyed, and the middle untouched, no advantage would be gained by operating in La Faye's manner, as Larrey conceives that the detached flap would slough, or become, as he terms it, disorganised. He now prefers dividing the middle piece of flesh, and giving the flaps the same shape as if they were uninjured. He even asserts, that the operation, done without any flaps at all, answers better than any method in which the surgeon preserves flaps not naturally intended for the part. Thus, when all the flesh of the shoulder has been shot away, he has seen surgeons cover the glenoid cavity with a flap saved from the

soft parts of the axilla; but such flaps invariably sloughed, hemorrhages ensued, and the patients died. (P. 430, 431.) Some of these latter observations are, clearly enough, the result of great partiality to a particular method of operating; because who can doubt, when the lateral parts of the shoulder are injured, as they frequently are (and not very rarely, as Larrey asserts), by the passage of a musket-ball through the shoulder, from before backwards, that the right method is that of La Faye; or the same operation, with the slight difference of making the flap of a semicircular shape? It was for cases of this description that Mr. Collier and the author of this Dictionary operated after La Faye's plan, with perfect success, after the battle of Waterloo: and a poor fellow of the rifle brigade, who was brought in too late for operation, and died of sloughing, had his shoulder injured in the same way, the middle of the deltoid being untouched, and shot-holes existing behind, and in front of, the articulation. The cases which have fallen under my own personal observation, and numerous others on record, furnish an adequate proof, that, excellent as Larrey's method is for many cases, La Faye's answers very well in others. After the storming of St. Sebastian, nine shoulder-joint amputations were done with success; seven of them by raising the deltoid as a flap. (See *Guthrie on Gunshot Wounds*, p. 103.)

The oval operation is described by M. Scouteten, for the left arm, as follows:—The surgeon first takes hold of the middle of the arm with his left hand, and raises it four or five inches from the side. With his right hand he then applies the point of the scalpel immediately below the acromion, and passes it into the flesh until it touches the head of the humerus. He then depresses the handle, and forms the first incision, which extends downwards four inches from the point of the acromion, and divides the posterior third of the deltoid, and the greater part of the fibres of the long portion of the triceps down to the bone. The second incision is next commenced with the point of the knife directed downwards upon the inner side of the limb, and in front of the biceps, on a level with the place where the first incision ended. The wound is then extended inwards and upwards to the acromion, where it terminates by joining the first. These two wounds form a triangle, which partly consists of relinquished integuments, and has its base downwards.

In order to find the joint with greater ease, the surgeon may now detach a little of the deltoid from the bone. An assistant can also keep the edges of the incision asunder, so that the operator may be enabled to see and divide the capsular ligament and the tendons of the supra-spinatus, infra-spinatus, and teres minor, which are inserted into the greater tubercle of the humerus, and the tendon of the subscapularis, which is inserted into the lesser tubercle. The operator, who constantly keeps hold of the arm, now communicates to it some rotatory movements, in order to bring the above tendons, one after another, under the knife, and divide them with the capsule. Immediately the capsule and tendons have been cut through, the head of the bone readily quits its socket. The surgeon luxates the bone by pushing it a little upwards, and, at the same moment, inclining the condyles towards the side. The next proceeding is to divide the flesh on the inner side of the limb,

as closely as possible down to the bone ; but, when the knife approaches the artery, this vessel is to be taken hold of and compressed by an assistant, before the incision is completed. In this way, no hemorrhage need be apprehended.

When it is the right limb, the only difference is, that the first incision is made at the inner side of the arm, and extended up to the acromion. Scoutteten considers a single assistant sufficient, and compression of the subclavian artery unnecessary. (*H. Scoutteten, La Méthode Ovalaire, ou Nouvelle Méthode pour amputer dans les Articulations.* Paris, 1827, 4to.)

[With respect to the choice between the different methods of amputation proposed for the shoulder-joint, it is scarcely necessary to repeat, that no one operation can be employed exclusively in all cases, but the selection must be influenced by the state in which the soft parts are found in each particular instance; for example, when the tissues on the outside of the joint are much injured, a flap from the deltoid would be impossible, and anterior and posterior flaps, or Larrey's or Guthrie's oval incisions must be resorted to instead. On the other hand, when a musket-ball has passed through the shoulder so as to injure the parts in front and behind, the operations just alluded to must give place to the external flap formed from the deltoid muscle, as recommended by La Faye, Dupuytren, &c.]

The double flaps and the oval incisions have the advantage of leaving a smaller cicatrix, which forms merely a single vertical line of wound, and is less extensive than after the single flap operation, where it is either square or semicircular in outline. The circular operation is more difficult of performance than the other methods, and, notwithstanding the recommendation of M. Velpeau, is very rarely practised. In cases of tumors of the arm requiring amputation at the shoulder, the oval incision will be found most convenient, as the disease which necessitates the operation will almost always extend too high to admit of the formation of flaps by transfixion. In a case of extensive disease of the humerus, in which the tumor was equal in size to the trunk of the patient's body, the present editor removed the limb, with great facility, by incisions of this kind, and notwithstanding the magnitude of the disease, the wound healed by first intention, and left a very small cicatrix.]

When the scapula is shattered, of course the loose fragments should be taken away ; and, if the acromion be broken, and the remnant of it pointed and irregular, this sharp rough portion should be sawn off, as was practised long ago by M. Faure. (See *Mém. de l'Acad. de Chir.* t. vi. p. 114.) In one case, indeed, Larrey found it necessary to take away more than two thirds of the scapula, and the humeral end of the clavicle. (*Mém. de Chir. Mil.* t. iv. p. 432.) Sawing off part of the acromion, and coracoid process, as a general rule, seems to me quite unnecessary and improper, not only as producing delay, but wounding other parts which should not be at all disturbed. (See *Guthrie on Gunshot Wounds*, p. 285, 286, &c.) The practice of scraping away the cartilage of the glenoid cavity, except when it is diseased, is not of greater value.

[Cases have occurred in which it was necessary to remove the whole of the scapula with the upper extremity. This was done successfully by Mr. Cuming in 1808, at Antigua, in a case of gunshot wound. In 1830, Gaetani Bey, at Cairo,

removed the whole of the scapula and half of the clavicle in a boy fourteen years of age. The case was one of extensive injury ; after amputation at the glenoid cavity the scapula being much shattered was cut away, and then the clavicle, being found to project too much, was partially removed. The patient recovered. (See *Fergusson, Op. Surg.* p. 338.) In 1844, M. Rigaud of Strasbourg, removed the entire scapula, with the external extremity of the clavicle, with complete success, in a soldier aged 51, for an osseous tumor on the anterior angle of the left scapula. In this case the arm had been removed at the shoulder-joint eight months previously for a tumor on its upper portion. (See *Velpeau, El. de Méd. Opér.* vol. ii. p. 471, Mott's Translation.) Several cases also are recorded of recovery taking place after the arm with the scapula had been completely torn away by machinery. (*Fergusson, loc. cit.*, and *Ed. Med. Journ.* Feb. 1845.)]

LOWER EXTREMITY.

[AMPUTATION OF THE TOES.]

[Amputation of the phalanges of the toes may be performed in the same way as in the fingers.]

Amputation of the toes at the metatarso-phalangeal joints may also be performed, as in the fingers, either with *lateral flaps*, or by the *oval method*.

In the *great toe* the large size of the head of the metatarsal bone should be remembered, or the operator may find that he has not left sufficient skin to cover it without an undue tension of the flaps. In this joint *upper and under flaps* will be found to answer remarkably well, and the thick pad of skin under the ball of the great toe will then be preserved uninjured. A method suggested by Mr. Skey produces a very similar result. He makes a longitudinal incision along the inner side of the toe, commencing about half an inch behind the articulation, and carried onwards to the middle of the first phalanx. At the end of this line he makes a circular incision round the toe down to the bone and then reflects back the integuments. (*Op. Surg.* p. 378.) The head of the metatarsal bone when implicated in the disease or injury should be removed with the saw or with the cutting forceps. If this is to be done, the incision may commence a little more posteriorly, but the head of the bone should always be retained if possible, as it forms the principal point of support at the anterior part of the foot.

All the toes may be separated from their metatarsal bones by a proceeding similar to that recommended for the fingers.]

[AMPUTATION OF THE TOES TOGETHER WITH THEIR METATARSAL BONES.]

[The *great toe* with its metatarsal bone may be removed by the oval incision recommended for the thumb or little finger. The point of the oval should commence half an inch behind the joint, or it will be difficult to disarticulate the metatarsal bone from the internal cuneiform without notching the skin. To avoid this inconvenience M. A. Guérin suggests that an incision should be made from the point of the oval downwards towards the inner margin of the sole of the foot, and over the articulation, thus forming an angular flap which may be turned down. (*Chir. Opér.* p. 146.)

In this operation it will be necessary to bear in

mind that the base of this metatarsal bone has a tubercle projecting downwards in the sole of the foot, and that this tubercle receives the insertion of the peroneus longus tendon.

The fifth toe with its metatarsal bone, may be disarticulated by a like method from the cuboid. The joint between these bones has an oblique direction forwards and inwards across the foot, and the base of the metatarsal bone has a large tubercle projecting backwards beyond it which may be very readily felt along the outer margin of the foot. This tubercle receives the insertion of the peroneus brevis tendon; the point of the knife should be passed behind it and then carried obliquely forwards, so as to divide the tendon and enter the joint.

The first and second toes with their metatarsal bones may be removed together; and so also may the fourth and fifth, or perhaps even the third, fourth and fifth; but if more than these should require to be taken away, it would be better to amputate across the foot at the tarso-metatarsal joints.]

AMPUTATION AT THE TARSO-METATARSAL ARTICULATIONS.

Mr. Hey proposed a new mode of removing the metatarsal bones, which on repeated trial fully answered his expectations. By the term *new*, I here mean a particular method, which had not been previously described, though it may have been performed by others sooner than by Mr. Hey himself; for the merit of having first done it is imputed to the late Mr. Turner, of North Yarmouth, who did it with success about the year 1787. (See *Hutchinson's Prac. Obs.* p. 70.) On the first entrance of the French army into Holland after the revolution, Paroisse met with many cases in which the toes, and more or less of the foot were attacked with mortification from cold. Here he found it sufficient merely to take away the diseased portion of the foot, and all the patients operated upon in this manner were cured; walking afterwards with more or less difficulty, according as the portion of the foot taken away had been greater or smaller. (*Opusculum de Chir.* p. 218.)

Mr. Hey made a mark across the upper part of the foot, to denote where the metatarsal bones are joined to those of the tarsus. About half an inch from this mark, nearer the toes, he made a transverse incision, through the integuments and muscles covering the metatarsal bones. From each extremity of this cut, he made an incision along the inner and outer side of the foot to the toes: he removed all the toes from the metatarsal bones, and then separated the integuments and muscles forming the sole of the foot, from the inferior part of the metatarsal bones, keeping the edge of the knife as near the bones as possible, in order to expedite the operation, and preserve as much muscular flesh in the flap as could be saved. He then separated the four smaller metatarsal bones, at their junction with the tarsus, and divided with a saw the projecting part of the first cuneiform bone, which supports the great toe. The arteries being tied, Mr. Hey applied the flap, which had formed the sole of the foot, to the integuments which remained at the upper part, and kept them in contact with sutures. The cicatrix being situated at the top of the foot, is in no danger of being hurt; while the place, where the toes were situated, is covered with such strong skin, viz. what previously formed

the sole of the foot, that it cannot be injured by any moderate violence. (See *Practical Observations in Surgery*, p. 535, &c.)

[Lisfranc, who gave very minute instructions for the performance of this operation, did not saw off the internal cuneiform bone, nor is it usual to do so in the present day; but the first metatarsal bone is separated, like the others, at its line of union with the tarsus. Before attempting this operation, the surgeon must make himself thoroughly acquainted with the anatomy of the tarso-metatarsal joints, which are very closely and firmly held together by ligaments, so that very little movement is permitted to them.

The general direction of the articulation is convex towards the toes, but it is also oblique forwards and inwards across the foot. This should be remembered in making the first incision, which should be slightly convex, and should have a corresponding obliquity instead of being transverse as recommended by Mr. Hey. Before making this incision the operator should determine to his satisfaction the points opposite to which the articulation commences, both on the inner and on the outer side of the foot. On the outer side he will have no difficulty in recognising the tubercle of the fifth metatarsal bone, but on the inner side there is no equally evident projection belonging to the first metatarsal; he might, therefore, unless he were well acquainted with the anatomy of these joints, fall into the error of opening the articulation between the scaphoid and cuneiform bones, instead of that between the cuneiform and first metatarsal. The principal prominence along the inner margin of the foot belongs to the tuberosity of the scaphoid bone, the joint between the metatarsal bone and the internal cuneiform is an inch and a quarter or an inch and a half in front of this prominence.

The outline of these articulations is very irregular in consequence of the manner in which the second metatarsal bone projects backwards and is wedged in between the three cuneiform bones. This point should be specially noticed, as it constitutes the chief difficulty in disarticulating the bones. There are very strong ligaments in the sole of the foot binding the bones together, passing both in a transverse and longitudinal direction, and the tendon of the peroneus longus crosses the sole of the foot to be inserted into the base of the first metatarsal bone. The French surgeons describe an interosseous ligament passing from the outer surface of the internal cuneiform to the base of the second and third metatarsal bones, and Lisfranc believed this ligament to be the principal obstacle in separating the bones. He recommended, therefore, that the point of the knife should be thrust downwards towards the sole of the foot, between the internal cuneiform and second metatarsal bones so as to divide this ligament, immediately after the joint had been opened above. This plan is not generally recommended by English writers, probably from fear that the point of the knife might pass too far into the sole of the foot, and injure vessels at a distance from the surface of the wound and beyond the reach of a ligature. A little practice on the dead subject will enable the surgeon to separate the bones with tolerable facility without resorting to this expedient. The plantar flap should be large; it should extend forwards on the inner side nearly to the root of the great toe, but it need not be quite so long towards the outer border of the foot.

In cutting this flap from within outwards after he has separated the joints, (which is the plan usually recommended,) the operator will find it difficult to make it of the exact shape required, and to give it an even and regular edge. He may avoid this difficulty by making an incision through the integuments of the sole to determine the outline of the flap, at the commencement of the operation.

To avoid the difficulties connected with the disarticulation of the second metatarsal bone, Mr. Skey suggests that it should be divided with the cutting forceps, and its posterior extremity be allowed to remain. (*Op. Surg.* p. 376.) M. Baudens has proposed that the first metatarsal bone only should be separated at the joint, the four others being sawn off in a transverse line at the level of the internal cuneiform bone. (*Bourgéry, Méd. Opér.* t. i. p. 267.)

Any additional length which can be given to the foot will be of the greatest advantage to the patient; it should therefore be understood that in any case which would admit of the preservation of the posterior half or posterior third of the metatarsal bones, amputation in the continuity of these bones should always be preferred to their disarticulation.]

AMPUTATION THROUGH THE MEDIOTARSAL ARTICULATIONS, OR CHOPART'S OPERATION.

The method of removing a part of the foot at the junction of the two halves of the tarsus, or Chopart's operation, is one of considerable merit. It is performed in the nearly parallel articulations of the os calcis with the os cuboides, and of the astragalus with the os naviculare. Thus the heel is preserved, on which the patient can afterwards walk. The performance of it is simple. The tourniquet having been applied, the surgeon is to make a transverse incision through the skin which covers the instep, two inches from the ankle joint. He is to divide the skin, and the extensor tendons and muscles, in that situation, so as to expose the convexity of the tarsus. He is next to make on each side a small longitudinal incision, which is to begin below and a little in front of the malleolus, and is to end at one of the extremities of the first incision. After having formed in this way a flap of integuments, he is to let it be drawn upward by the assistant who holds the leg. There is no occasion to dissect and reflect the flap; for the cellular substance connecting the skin with the subjacent aponeurosis is so loose, that it can easily be drawn up above the place where the joint of the calcaneum with the cuboides, and that between the astragalus and scaphoides, ought to be opened. The surgeon will penetrate the last most easily, particularly by taking for his guidance the eminence, which indicates the attachment of the tibialis posticus muscle to the inside of the os naviculare. The joint of the os cuboides and os calcis lies pretty nearly in the same transverse line, but rather obliquely forward. The ligaments having been cut, the foot falls back. The bistoury is then to be put down, and the straight knife used, with which a flap of the soft parts is to be formed under the tarsus and metatarsus, long enough to admit of being applied to the naked bones so as entirely to cover them. It is to be maintained in this position with three or four sutures and strips of adhesive plaster, which are to extend from the heel, over the flap, to the inferior and anterior part of the leg. On the instep, the continuation of the anterior tibial artery will require

a ligature; and in the sole, the internal and external plantar arteries, in the thickness of the flap of soft parts, must generally be taken up. I have seen several patients who had undergone Chopart's operation, and afterwards walked exceedingly well. A black man was lately shown to me by my friend, Mr. Copland Hutchison, who had performed the operation; and in reality scarcely any limping was perceptible. I mention these facts, because Dupuytren may have expressed himself rather too strongly against Chopart's operation, when he says, that the removal of a part of the tarsus deprives the patient of a point of support essential in walking and standing, and renders the limb nearly useless. He asserts likewise, that, as the attachments of the tibialis anticus and tibialis posticus, the antagonists of the gastrocnemius and soleus, are divided, the heel becomes drawn considerably upwards.

[The operation is still practised very much in the manner just described, excepting that the superior incision is commonly made slightly convex and not square in shape. It should commence on each side near the margins of the sole of the foot and a little in front of the articulations. On the inner side of the foot the tuberosity of the scaphoid forms a sure guide to the joint between that bone and the astragalus, while on the outer side the joint between the cuboid bone and the os calcis will be found with tolerable certainty three-quarters of an inch behind the prominence of the fifth metatarsal bone. Should the condition of the parts in the sole not permit the formation of a sufficient flap from that region, part of the covering might be obtained from the dorsal surface of the foot; but the large flap from the sole is much to be preferred, because it removes the cicatrix from the lower end of the stump, where it is most exposed to injury. Some surgeons saw off a thin slice of the astragalus and os calcis. M. Malgaigne, with more reason, thinks it advisable to remove the projecting anterior and external angle of the os calcis, which rests on the ground when the heel is retracted, and causes painful pressure upon the flap. He is doubtful even whether, on account of this tendency to retraction, it would not be always preferable to take away the os calcis and leave only the astragalus. (*Méd. Opér.* p. 310.)

The retraction of the heel by the unopposed action of the muscles of the calf is no doubt one of the principal objections to this operation. Mr. Fergusson relates one case, where he found it necessary, principally on account of this retraction, to amputate a second time at the ankle joint. (See *Pract. Surg.* p. 487.) Nevertheless, excellent stumps do frequently result from Chopart's operation, and if any tendency to retraction of the heel should become manifest during the progress of the cure, it may be prevented by the subcutaneous section of the tendo achillis. This expedient has been frequently resorted to, and with perfect success. The retraction of the heel is spoken of by M. Velpeau as an exceptional occurrence; he states that it did not occur in any of the cases (five in number) operated on by him; and M. Blandin says that he met with it but once out of the eleven of these amputations which he has performed. The case above alluded to was also the only instance of painful stump, after Chopart's operation, which Mr. Fergusson has met with.

Cases sometimes occur in which the scaphoid bone can be preserved; others in which both scaphoid and

cuboid can be retained. For these it is almost impossible to lay down rules with precision, but the necessary modifications in the incisions will suggest themselves to every intelligent surgeon.

Mr. Syme objects to partial amputations through the tarsus in cases of caries, on account of the liability to recurrence of the disease in those bones which remain, although they may appear perfectly sound at the time of the operation. He states that he once performed three secondary amputations, within a period of twelve months, upon stumps in which Chopart's operation had been practised. (*Lancet*, vol. i. 1855, p. 307.) This objection, does not hold good in cases of injury, in which these partial amputations through the foot have, perhaps, their most valuable application.]

[AMPUTATION AT THE ANKLE-JOINT.]

[In cases of caries of the tarsal bones, beyond the limits of Chopart's operation, and in many cases of injury to the foot, amputation at the ankle-joint is now performed.]

This amputation has during the last fifteen years been brought prominently into notice by Mr. Syme, and the name of this gentleman is now very commonly associated with it. Previously to this, it had been practised occasionally by continental surgeons; in the last century by Sedillier, Rossi, and others, and in the present century by M. Baudens; so little, however, was it thought of, that in former editions of this work, it was passed over altogether without notice.

The principal novel feature in the method adopted by Mr. Syme, was the procuring a flap "from the sole of the foot and thick integument of the heel, so that the dense textures provided by nature for supporting the weight of the body, might be still employed for the same purpose."

Previous to this, the thin skin from the sides of the joint or from the instep, had been made use of to form the flaps, and, consequently, the stump was not well adapted to bear continuous pressure. Originally too the malleoli were allowed to remain, so that it is not surprising that the results were unsatisfactory. The removal of the malleoli was first suggested by M. Baudens; but in his operations the flap was cut in the form of a gaiter from the skin on the dorsum of the foot, and was turned downwards over the ends of the bones. The delicate integument from the dorsum of the foot was not likely to answer well as a covering for a stump, which must necessarily have to bear the whole weight of the body.

The following is Mr. Syme's account of his first operation, Sept. 8, 1842, on a patient aged sixteen, with caries of the tarsal bones. "I cut across the integuments of the instep in a curved direction, with the convexity towards the toes, and then across the sole of the foot, so that the incisions were nearly opposite to each other. The flaps thus formed were next separated from their subjacent connections, which was easily effected, except at the heel where the firmness of the texture occasioned a little difficulty. The disarticulation being then readily completed, the malleolar projections were removed by means of cutting pliers. The patient suffered no constitutional disturbance or alarming symptom after the operation. A small slough separated from the edge of the lower flap, in which, as well as the upper one, I

found it necessary, during the healing process, to make a counter opening for the free discharge of matter." The patient left the hospital on the 2nd December. The wound was soundly healed; "and any degree of pressure could be borne by the stump, which had a round form well suited for the adaptation of a boot or artificial foot, and was strongly protected from external injury by its thick integuments." (*Lond. and Ed. Month. Journ.* Feb. 1843).

In 1844, Mr. Syme published the following further directions, having found that in his first operations, the flap was made unnecessarily long. "The incisions across the instep and sole of the foot should be curved, the convexity forwards, and exactly opposite each other. A line drawn round the foot, midway between the head of the fifth metatarsal bone and the malleolus externus, will show their extent anteriorly; and they should meet a little further back, opposite the malleolar projections of the tibia and fibula. Care should be taken to avoid cutting the posterior tibial artery before it divides into its plantar branches, as in two cases where I did so there was partial sloughing of the flap. If the ankle-joint is sound, the malleolar processes should be removed with cutting pliers, but if the articular surfaces of the tibia and fibula be diseased, a thin slice of these bones should be sawn off. The edges of the wound should be stitched together and lightly dressed. When the cure is completed, the stump has a conical shape, and has for its apex or central point of pressure, the thick integument which covered the heel." (*Edin. Med. Journ.* Aug. 1844.)

Subsequently to this he again slightly modified his incisions so as further to reduce the size of the flap. "The foot being placed at a right angle with the leg, a line drawn from the centre of one malleolus to that of the other, directly across the sole of the foot, will show the proper extent of the posterior flap. The knife should be entered close up to the fibular malleolus, and carried to a point on the same level on the opposite side, which will be a little below the tibial malleolus. The anterior incisions should join the two points just mentioned at an angle of 45° to the sole of the foot and long axis of the leg. In dissecting the posterior flap, the operator should place the fingers of his left hand upon the heel, while the thumb rests upon the edge of the integuments, and then cut between the nail of the thumb and the tuberosity of the os calcis, so as to avoid lacerating the soft parts, which he, at the same time, gently, but steadily presses back, until he exposes and divides the tendo achillis. The foot should be disarticulated before the malleolar projections are removed, which it is always proper to do, and which may be most easily effected by passing a knife round the exposed extremities of the bones, and then sawing off a thin slice of the tibia connecting the two processes." (*Ed. Monthly Journ.* 1846.)

"It is of the greatest importance in separating the flap of skin from the os calcis, to cut parallel to the bone, since when the flap is detached from the bone, its only supply of nourishment must be the branches which run through it parallel to its surface, and if instead of keeping parallel to the surface, the operator cuts on the flap, he will by scoring it in this way necessarily cut across these branches." Very light dressings should be used for the first few days, as it is important to avoid as much as possible the application of pressure; "tight

bandaging would of itself be sufficient to kill the flap." (See *Lancet*, vol. i. 1855, p. 307.) Mr. Syme insists that the flap should be completely separated from the os calcis before the joint is disarticulated; he strongly disapproves of the plan which some have adopted of first cutting through the joint, and then dissecting the flap from behind forward off the os calcis, believing that the vessels are more likely to be injured by so doing.

Some modifications in the operative procedure have been since suggested. Mr. Quain, in order to facilitate the dissection of the flap, proposes, "after the incision from malleolus to malleolus under the os calcis, to make a straight incision at right angles with the first, to the back part of the heel on the outer side of the foot, a little above and parallel with its outer margin." (See *Med. Times*, Oct. 10, 1857, p. 370.) Dr. Handyside has suggested "antero-lateral flaps," the incisions commencing in front of the joint and terminating in the centre of the sole of the foot, just in front of the ball of the heel. The cicatrix would be vertical in direction and placed anteriorly. The thick integument of the heel would still form the basis of support. The late Dr. R. J. Mackenzie proposed to form an internal lateral flap in the following manner:—"The point of the knife is entered in the mesial line of the posterior surface of the ankle on a level with the articulation, carried down obliquely across the tendo Achillis towards the external border of the plantar surface of the heel, along which it is continued in a semilunar direction. The incision is then curved inwards across the sole of the foot, and terminates on the inner side of the tendon of the tibialis anticus, about an inch in front of the inner malleolus. The second incision is carried across the outer aspect of the ankle in a semilunar direction between the extremities of the first incision, the convexity downwards, and passing half an inch below the external malleolus. The flap is now dissected up, care being taken that the knife cuts close to the bones, so as to preserve the whole thickness of the soft parts. By holding the base of the flap between the fingers and thumb, as it is detached from the bones, all risk of wounding the artery is avoided. The foot is then severed at the articulation, and the ends of the tibia and fibula cleared, so as to allow of the application of the saw, by which a thin slice of the extremities of the bones is removed, as in Syme's operation. The stump which is left differs from that formed by Syme's operation only in the situation of the cicatrix, which is here on the fibular side of the stump. With an artificial foot, the patients are able to walk with ease, and with slightly perceptible lameness, the weight of the body resting on the face of the stump." (*Ed. Monthly Journal*, Aug. 1849.) Dr. Mackenzie had operated in this way twice, and Dr. MacLagan three times, with satisfactory results, but in one case in which the posterior tibial artery was wounded the flap sloughed. The only merit claimed for this operation over that of Mr. Syme is its greater facility of performance, and its adaptation to cases where the integuments on the outer side of the foot are diseased, as they not unfrequently are. M. J. Roux has also proposed an operation very similar to that just described. (See *Malgaigne, Méd. Opér.* p. 314.)

Mr. Syme believes amputation at the ankle-joint to be applicable to many cases of disease or injury of the bones of the foot, or even of the ankle-joint

itself, in which formerly it was customary to remove the leg just below the knee. An extended experience of it has convinced him, that a very useful stump will be obtained, well calculated for bearing pressure in consequence of the thick integuments of the heel being made use of to cover the ends of the bones, and that with the aid of an artificial foot the patients will be able to walk without difficulty, and with no very serious degree of lameness.

The principal advantages claimed for this operation by Mr. Syme are; first, that no more of the limb is removed than is absolutely necessary, the diseased portion alone being taken away, and consequently the danger to life is reduced to the lowest possible degree; secondly, that the risk of exfoliation of bone from inflammation of the medullary membrane and of phlebitis is lessened, because cancellated instead of dense bone is sawn through, and the medullary canal is not exposed; thirdly, that the stump is able to bear the weight of the body in progression, without pain or inconvenience. The first of these advantages would be of greater importance, if amputation through the calf of the leg were necessarily the alternative, for Mr. Syme is no doubt correct in thinking, that the risk to life is much less in amputating at the ankle-joint than in amputating below the knee at the usual place of election; and it is with amputation at this level that he has always drawn the comparison. The comparison, however, should rather be made between amputation at the ankle and amputation in the lower third of the leg, and then the difference in risk will not be very appreciable, or will even be in favour of the amputation in the lower third of the leg. In fact, in this latter situation, although an inch or two more bone is taken away, the wound is considerably smaller than in amputating at the joint, and it will certainly heal with much greater facility. Neither will many surgeons attach much importance to the alleged advantage of sawing through the bone in its cancellated texture; Mr. Syme himself does not now persist in advocating it in all cases. (See AMPUTATION OF KNEE-JOINT.) The main advantage then of amputation at the ankle consists in the usefulness of the stump which is formed, and in this particular it seems to be deserving of all that has been said in its favour by Mr. Syme and others. The stumps after ankle-joint amputations are in fact almost the only ones that can be at all relied on, for supporting the weight of the body.

The principal objections which have been urged against it are, its difficulty of performance, the tendency to sloughing of the flap, and the slowness with which the wound is found to heal even under the most favourable circumstances. The first of these objections, namely, *difficulty in the operative procedure*, is not one of any great moment, since any surgeon with moderate powers of manipulation will, with a little practice, be enabled to perform it with ease. The liability to *sloughing of the flap* is a more important disadvantage; it has seldom, however, been of any great extent, and though it has of course delayed the cure, it has not much interfered with the subsequent usefulness of the stump. According to Mr. Syme it is more frequently the fault of the operator than of the operation. The delay which often occurs in the healing of the wound is another, and perhaps more serious inconvenience; for it is useless to anticipate that so extensive a

flap will unite by the adhesive process. Apposition of its edges may be obtained, but contact throughout its interior is manifestly impossible, and collections of matter to a greater or lesser extent are nearly certain to take place.

In these respects then amputation at the ankle-joint is inferior to amputation in the lower third of the leg; and for these reasons, the latter operation should be preferred in persons of broken down constitution or in those advanced in life, where sloughing of the flap would be more likely to take place; and in whom either the presence of a sloughing wound, or the long delay in the healing process might be attended with dangerous consequences. But in young persons, and in those whose state of health is tolerably good, the inconveniences attending amputation at the ankle-joint are more than compensated for by the preservation of a limb on the end of which the patient can support the weight of his body, and which will enable him to wear a much less cumbersome and expensive artificial contrivance.

Capability of supporting pressure, however, being the main advantage of amputation at the ankle, it is obvious that it ought never to be done unless the skin of the heel can be obtained to form the flap. When this is impracticable, the lower third of the leg should be preferred; for if the stump be left longer than this, it will not only interfere with the mechanism of the artificial limb, but it will also be difficult so to construct the latter that it shall not cause painful pressure on the end of the stump.

Very many surgeons have now adopted this operation, but the opinion of the profession respecting it is, nevertheless, still somewhat unsettled. Mr. Quain says, the operation appears to him "to be free from any valid objection, and, what is more important, the result in practice has been found to be good. A person who has undergone this operation is enabled to bear his whole weight upon the end of the stump without inconvenience; and, on this account, the facility of progression is, with a proper apparatus, decidedly greater than when the amputation is performed at any higher part of the limb. (*Med. Times*, Dec. 27, 1851, p. 659.) Mr. Erichsen thinks it "constitutes one of the greatest improvements of recent date in operative surgery, as by its performance amputation of the leg may often be avoided, and the patient being left with an exceedingly useful stump, the covering of which being ingeniously taken from the heel, constitutes an excellent basis of support." (*Science and Art of Surg.* 1853, p. 71.) Mr. Fergusson stated (in 1851), that he had operated eight times, and that Mr. Busk, had had a like number of cases. Mr. Fergusson was then strongly in favour of it, believing the stump to be "the best that can be made in the lower extremity" (see *Med. Times*, vol. i. 1851, p. 640), and subsequently he says, "I have now had considerable personal experience in this operation, and do not hesitate in giving it my strongest recommendations." (See *Prac. Surg.* ed. 3, 1852, p. 491.) He has since, however, greatly modified these opinions, and he now says, "what with violent inflammation extending up the leg, sloughing, secondary hemorrhage, death immediately dependent on the operation, tardy healing of the wound, and defective condition of the stump from languid circulation and tenderness, so that it could not be

pressed upon, I have formed a most unfavourable impression against it." (See *Prac. Surg.* ed. 4, 1851, p. 487.) Mr. Butcher, of Dublin, mentions a case, in which he amputated at the ankle-joint, and was obliged three months afterwards to remove the leg below the knee, in consequence of ulceration of an excessively painful character taking place in the stump. "He thinks it still remains to be proved that the operation at the ankle-joint affords the most comfortable and useful stump to the labouring man, and promises less risk to life. He has seen the operation performed three times, and in no one case was it attended with success." (*Dublin Quarterly Journal of Med. Science*, August 1851.)

Mr. Simon has modified the operation at the ankle-joint in two cases, by allowing the astragalus to remain. His first case was in May, 1848, in a patient aged fifteen, with scrofulous caries and necrosis affecting the front and outside of the tarsus, extending even to the os calcis, but sparing the astragalus. The operation was performed in the same way as is generally adopted for amputation at the ankle-joint, the knife being passed between the astragalus and os calcis instead of between the astragalus and the lower extremity of the tibia and fibula. The flap was taken in the same manner as in the ordinary amputation of the ankle-joint, and the stump turned out remarkably good and useful. Mr. Simon considers that it was better than the stump left after Chopart's operation, because it was undisturbed by muscular contraction, and better than Syme's because of its greater breadth, its mobility in the joint, and its additional inch and a half in length. This stump has been seen for several years, and it was found that it had worked very advantageously for the patient. The second case was for a railway injury of the foot, in 1853. The same operation was performed as in the preceding case, but the man died of tetanus. When he was seized with this affection, a fortnight after the operation, the entire stump had very nearly healed, and, in prospect of firmness and position of cicatrix, was as near a model stump as any one could have wished to see. (*Lancet*, vol. i. 1854, p. 100.)

M. Malgaigne, also, has amputated beneath the astragalus on two occasions, and with successful results. His mode of proceeding, however, was different. He made a large internal flap, composed of the parts from the inner concave surface of the os calcis, together with about two-thirds of the breadth of the sole of the foot. This flap must extend forwards, some distance in front of the astragalo-scaphoid articulation, in order to leave a sufficient covering for the rounded head of the astragalus. (*Méd. Opér.* p. 310, ed. 5.)

M. Pirogoff, of St. Petersburg, has proposed another modification, the effect of which is to preserve the posterior portion of the os calcis in the flap. After the incisions have been made in the manner proposed by Mr. Syme, the ankle-joint is opened in front, and the foot disarticulated. The os calcis is then sawn through from above downwards, behind its articulation with the astragalus. The portion of bone forming the heel remains, therefore, in the flap, and is to be brought forward and turned up, with the view of making it unite with the sawn surface of the lower end of the tibia.

This operation has been performed in London

by Messrs. Ure, Simon, and Partridge, and six times in the Dreadnought Hospital Ship by Messrs. Busk and Tudor. Mr. Ure's patient died from cerebral disease before the stump had healed. Mr. Simon's case and Mr. Partridge's case were attended with successful results. Of Messrs. Busk and Tudor's cases four are said to have recovered with excellent stumps, but the other two terminated fatally. In the four successful cases operated on by those gentlemen, "the posterior part of the os calcis was united firmly with the tibia, generally in about three weeks; but in one instance, union was good at the end of twelve days." The os calcis was sawn obliquely downwards and forwards "in a line from the posterior margin of its upper articulating surface to the under edge of the articulating surface of the cuboid." (See *Remarks on Pirogoff's operation*, by J. Croft. *Lancet*, Feb. 6, 1858, p. 136.) In the only case witnessed by the writer, the heel was strongly drawn backwards by the unopposed action of the muscles of the calf, and no amount of force would produce the required contact between the osseous surfaces.

Mr. Syme has objected to this proposal; first, that the os calcis is a bone predisposed to caries, and it is therefore undesirable to leave any part of it; secondly, that the operation is not facilitated; thirdly, that union of the osseous surfaces is not likely to take place easily; fourthly, and principally, that the integuments of the heel are necessarily carried forwards, and the end of the stump is covered by skin, which is not destined for sustaining the weight of the body. (*Lancet*, vol. i. 1855, p. 307.) M. Pirogoff himself is said now to have abandoned it, in favour of the ordinary amputation at the ankle-joint. (See *Fergusson, Pract. Surg.* ed. 4, p. 487.)

Mr. Syme also objects to the retention of the astragalus, "on account of its predisposition to caries; one of the great recommendations of amputation at the ankle being, in his opinion, that it removes all the bones which are liable to the disease." (*Lancet*, vol. i. 1855, p. 307.)

AMPUTATION OF THE LEG.

In treating of amputations in general, it has been remarked, that as much of the limb as possible should be preserved. The longer it is after the operation, the stronger and more useful will it be found. But when the leg is to be amputated, it has been a very general custom to operate a little below the knee, even though the disease for which the limb is removed may be situated in the foot or ankle, and would allow the operation to be done much further down. The common practice has been to make the incision through the integuments, just low enough to enable the operator to saw the bones about four inches below the lowest part of the patella. This has been termed the place of election. About six inches below the patella would therefore be an eligible place for the first circular cut through the skin. It has been alleged as a reason for this mode of proceeding, that it is quite sufficient to preserve a few inches of the leg, in order to afford the body a proper surface of support in walking with a wooden leg; whereas, if a larger portion were saved, the superfluous part would be a great inconvenience both in walking and sitting down, without being of the smallest utility in any respect whatever. However, as I shall presently notice, experience proves that where the injury or

disease require it, amputation may be performed at a *much higher* level than was formerly sanctioned; and also, that in many cases of disease of the foot, or ankle-joint, amputation *near the ankle* may be substituted with advantage for the old operation a hand's breadth below the knee. It will be necessary to speak separately of amputation at each of these three situations, viz. 1. at the ordinary place of election; 2. between this and the knee-joint; 3. between this and the ankle-joint.

Amputation of the Leg at the "Place of Election."

Circular method.—The patient is to be placed on a firm table, and the sound limb fastened to the nearest leg of the table. The tourniquet is applied either to the femoral or popliteal artery; and the leg which is about to be removed being properly held by one assistant, while the integuments are drawn upward by another, the surgeon, with one quick stroke of the knife, is to make a circular incision through the integuments all round the limb. Some recommend the operator to stand on the inside of the leg, in order that he may be able to saw both bones at once. This is the old manner, which is still very generally followed. Many suppose that it diminishes the chance of the fibula being splintered, which is completely divided rather sooner than the tibia. But splintering the bones generally arises from the assistant depressing the limb too much, or the surgeon pressing too heavily on the saw. If this mismanagement were to occur, it would be difficult to explain why the tibia should not be splintered instead of the fibula, when a certain thickness of it had been sawn through. Velpeau considers that it would be a better rule to let the surgeon's position be such as will constantly enable him to take hold of the limb below the knee with his left hand; while Liston, on the contrary, preferred always to stand so that the left hand should steady the part to be removed during the application of the saw. [It is in reality a matter of no great importance on which side the surgeon stands, for if the one position gives him the advantage of his left hand to retract the soft parts, the other certainly enables him to hold the limb more steadily while he is sawing the bones.]

A circular cut having been made through the integuments, about two inches below the place where it is intended to saw the bones, the skin is dissected from the muscles and bones equally all round the limb, to the extent of about a couple of inches. The integuments are then turned up, and a division of the muscles made all round down to the bones, on a level with the line where the detachment of the skin has terminated. Any remaining muscular fibres are then to be divided together with the interosseous membrane, at a somewhat higher level, if possible, with the catlin, or long, narrow, double-edged knife, which is to be carried between and around the bones, until they are completely isolated; and it should also divide their periosteum at the point where it is intended to apply the saw. The soft parts are next to be protected from the teeth of the saw by a linen retractor, made with two slits to receive the two bones, care being taken to let the unsplit part be applied to the muscles of the calf.

Reckoning from before backward, the arteries requiring ligatures are:—1st. The anterior tibial, which lies close to the nerve, and in front of the interosseous ligament. 2ndly. The posterior tibial,

with the nerve on its fibular side. 3rdly. The peroneal: both these arteries being situated behind, between the soleus and the deep stratum of muscles,—the posterior tibial behind the external edge of the tibia, on the posterior surface of the flexor communis digitorum pedis, and the tibialis posterior; the peroneal behind the fibula, amongst the fibres of the long flexor of the great toe. 4thly. Sometimes two or more branches in the calf, termed sural. 5thly. Now and then the nutrient artery of the tibia. Frequently the anterior tibial artery retracts so far that it cannot be taken up without first dividing the soft parts concealing it. The occurrence is ascribed by M. Ribes to the double curve which the artery describes to get in front of the interosseous ligament; by M. Gensoul, to the retraction of the artery exceeding that of the muscles which adhere to the bone.

When the soft parts have been cut, the bones sawn, and the arteries tied, the wound is to be closed by bringing the flap of the skin over the stump, so as to form a line of wound corresponding to the transverse diameter of the limb. This should be done without letting any tight strap of plaster press the skin against the sharp edge of the tibia; a serious and hurtful practice, which has often occasioned ulceration and sloughing of the integuments, and protrusion and necrosis of the bone. It is this danger which led Mr. Guthrie to prefer closing the wound vertically, or nearly so, and applying the adhesive straps from side to side. And where a great deal of skin is saved all round the limb, and the muscles of the calf are not calculated upon for covering the bones, the perpendicular line of the wound will answer very well.

The practice is sometimes adopted of sawing off the sharp upper ridge of the tibia. It is advocated by A. C. Hutchison, Marjolin, and Ballard. It has the sanction of Mr. Guthrie, who says that, in thin persons, where the spine of the tibia is very sharp, this part should be removed with the saw (p. 222). In France, the removal of the front angle of the tibia is generally approved. (*J. F. Malgaigne*, op. cit. p. 291.)

Occasionally, surgeons have also removed the small remnant of the fibula, and such was sometimes the practice of Larrey, when he amputated nearer the knee than common. (*Mém. de Chir. Mil.* t. iii. p. 389.) This plan, however, is objectionable, as will be hereafter explained.

[The foregoing is the usual method of amputating the leg a hand's breadth below the knee by the circular incision. The late author, however, preferred the following method, which is in some measure a combination of the flap and circular operations; a flap being made from the muscles after the circular division of the skin:]—A circular cut having been made through the integuments, about two inches below the place where it is intended to saw the bones, the next object is to preserve skin enough to cover the front of the tibia, and the part of the stump corresponding to the situation of the tibialis anticus, extensor longus pollicis pedis, and other muscles between the tibia and fibula and those covering the latter bone. Throughout this extent there are no bulky muscles which can be made very serviceable in covering the end of the stump, and consequently the operator must take care to preserve sufficient skin in this situation, by dissecting it from the parts beneath and turning it up.

On the back part of the leg, on the contrary, the

skin should never be uselessly detached to a great extent from the large gastrocnemius muscle, which, with the soleus, will here form a sufficient mass for covering the stump. I am disposed to think it best, however, when the calf is bulky, to let a small quantity of skin be detached and saved at the back part of the leg, so that there may be a certainty of having enough to cover well the extremity of the divided gastrocnemius. As soon as the skin has been separated in front and on the outside of the leg the surgeon is to detach the skin from the calf for about an inch; and having reflected or drawn this preserved portion out of the way, he is to place the edge of the knife close to the edge of the retracted or reflected skin at the back of the limb, and cut obliquely upwards through the muscles of the calf, from the inner edge of the tibia quite across the fibula, supposing the operator to be on the outside of the right leg, and that it is this member which is undergoing removal. In performing this last incision, as M. Louis well observes, it is essential to incline the edge of the knife obliquely upwards. Thus the skin will be longer than the muscles, and the cure accelerated. (*Mém. de l'Acad. de Chir.* t. v. edit. in 12mo.) The flap, formed of the integuments and muscles of the calf, is then to be held back by one of the assistants, while the surgeon completes the division of the rest of the muscles, together with that of the interosseous ligament, by means of the double-edged knife.

Amputation by an oblique or oval incision.—The method recommended by M. Sedillot consists in dividing the integuments on the outer side of the leg obliquely, from before backwards, and from below upwards. The knife is then carried round the posterior part of the limb to its inner side from behind forwards, and from above downwards. The division of the integuments is next completed in front by a transverse incision, leaving an oval wound, with its anterior angle truncated.

The plan adopted by M. Baudens differs only from that of M. Sedillot in making the incision through the skin entirely oval, and letting the knife descend about an inch lower down in front than behind.

“One reason,” says M. Malgaigne, “not mentioned by any writer, makes me prefer the oval even to the circular method. In the latter, the principle is to leave the integuments sufficiently long on every side to cover one half of the stump. Now the posterior integuments, on the retraction of the muscles, reach the centre of the wound more readily than the integuments in front, which have to pass and bend over the end of the tibia. The object then can only be fulfilled by allowing a greater length to the skin in front.” (*Manuel de Méd. Opér.* p. 293.) Dr. Pancoast slopes the incision backward towards the popliteal region, about an inch higher than the incision on the tibia. He has less flabby skin, a neater junction, less suppuration, and makes a better stump. (See *Reese*, Amer. ed. 1851, Appendix, p. 20.)

Oval amputation of the leg can never be necessary, if care be taken in the other methods to save a sufficiency of the integuments in front of the limb, as advised in the descriptions already given of those operations.

Flap Amputation of the Leg.—[Amputation with a single flap cut from the posterior surface was originally proposed by Verduin, and is the method

which, with some modifications, is now commonly adopted by those who prefer flap amputations. The surgeon, passing his knife close behind the bones, transfixes the limb at or a little below the level at which he intends to apply the saw, and cuts a flap from the calf of the leg four or five inches in length. The angles of this flap are united by an incision, slightly convex downwards, across the anterior half of the leg. The skin in front is then dissected up for about half an inch, and retracted by an assistant, who also holds back the flap. The remaining muscles are divided and the operation finished as in the circular method. The soft parts are so readily held out of the way of the saw, that the retractor is usually dispensed with. The anterior incision may be made either before or after transfixion, at the option of the surgeon.]

The following was Mr. Liston's method. If the right leg was to be removed, he placed himself on its inner side, and grasped the lower part of the limb with his left hand, an assistant supporting the foot at a proper height. The knife was introduced over the outer side of the fibula, and carried upwards along that bone, for an inch and a half or two inches. It was then brought across the limb in a semicircular direction; and as soon as it reached the inner and lower part of the tibia, transfixion was performed by pushing the knife across the posterior surface of the bone, and out at the upper part of the fibular incision. By then carrying the knife downwards, a posterior flap was formed sufficient to cover the bones. The integuments on the fore part were then dissected upwards a little, with the same knife, so as to form a small semilunar flap. The muscles in the interosseous space were next cut through, and the knife carried round the bones in order to divide the soft parts.

[These amputations might be made to partake more of the character of double flap operations by not cutting so long a flap from behind, and by saving more skin at the anterior part of the leg; but they will then have the disadvantage that the cicatrix will be near the middle of the stump instead of at its anterior part; and also that the covering for the ends of the bones will not be of uniform thickness, in consequence of the greater bulk of the soft parts comprised in the posterior flap. Flap amputation of the leg is open to the objection that the flap will contain a thick unwieldy mass of muscle, which can with difficulty be kept applied over the surface of the stump, and in which the muscles will generally be cut at a lower level than the skin, so as to prevent the edges of the wound being brought into good apposition, unless some of the redundant muscular substance be removed. This is especially the case if the muscles are well developed; and if transfixion is practised close behind the bones, which is the plan most commonly recommended. For this reason, many surgeons who are not averse to flap operations in other parts, consider them unsuited to this region, and in this opinion the writer entirely coincides.]

Dr. Bushe, as already mentioned, conceives that it is only in amputating below the knee that the circular incision is decidedly preferable to the flap operation. He "never saw a case, where a flap was formed from the calf of the leg, in which considerable retraction of the remaining muscles did not ensue, attended with great induration of the flap, separation of its edge from the skin on the front of the tibia, sometimes exfoliation of the bone,

and generally tedious suppuration." (*Lancet*, No. 246, p. 208.) [Mr. South says, that "so far as his experience proves, flap operations in the continuity of the bone may be performed as successfully as circular operations on every limb but the leg, in which the calf muscles are so bulky that it is often difficult to get the skin well over them, if they be left, and he does not think the cure so quick as with the circular." (*South's Chelius*, vol. ii. p. 903.) And Mr. Syme, who was at one period a very strong advocate for amputation by flap in this situation, has, for reasons similar to those above stated, changed his opinion, and now employs the circular operation. Mr. Syme's incisions are, however, not exactly circular, but he forms a short anterior and posterior flap of integuments only, which being dissected up the muscles are cut by circular incision. He now divides the bone somewhat higher than usual (an inch or an inch and a half below the tuberosity of the tibia.) (*Lancet*, Feb. 1855, p. 203.)

To obviate the inconvenience arising from the presence of too much muscle, Mr. Skey recommends that a part only of the thickness of the calf should be included in the flap. "The leg being raised, the calf should be supported on the open palm of the left hand of the operator, by which it is flattened out considerably in breadth. The knife is then introduced through the skin at a depth of not more than half or three quarters of an inch above the palm of the hand, and passed straight across to the opposite side, and the posterior flap, which in addition to the integuments will thus include a small thin portion of the gastrocnemius, is formed of sufficient length to pass forwards around the end of the tibia. The anterior flap is now cut, but of small dimensions. A circular sweep of the knife round the limb is then made, which divides the rest of the calf, and the catlin is introduced through the deep muscles and interosseous membrane. (*Op. Surg.* p. 368.)]

[*External Flap.*—Some of the French surgeons recommend the formation of a flap composed of skin and muscle from the external side of the leg, and the result is stated to be satisfactory. The soft parts being drawn outwards, the limb is transfixed from before backwards and a flap is cut about four inches in length. In transfixing, the knife must be kept as close as possible to the outer side of the bones, due care being taken that it does not pass between the tibia and fibula. The angles of the flap are united by an incision slightly convex downwards on the inner side of the limb. (See *A. Guérin El. de Chir. Opér.* tom i. p. 176.)]

Amputation above the Place of Election.—The principal reasons have already been specified for the general custom of amputating the leg about four inches below the patella; and it was formerly the custom if the disease or injury would not admit of the operation being done thus low, to remove the limb above the knee-joint. In the Egyptian campaign, however, Baron Larrey performed two amputations very near the knee-joint, almost on a level with the head of the fibula, which he judged proper to extirpate. The successful result of these operations dispelled the fear which this experienced surgeon previously entertained about amputating in the thick part of the upper head of the tibia; for no caries of this spongy portion of the bone, no bad effects on the knee-joint, and no ankylosis of the stump ensued: and, with the difference of a few days, the wound healed as readily as

that made in the common place of election, viz. three or four finger-breadths below the tuberosity of the tibia. Since the above-mentioned campaign Larrey has adopted this practice in many cases, where it was impossible to have operated at the usual place; and he assures us, the success fully equalled what attends operations done at the ordinary distance from the knee. In 1806, another French military surgeon, who had tried this method himself, published a dissertation, in which he commended operating, where circumstances required it, much higher than the point allowed by generally received rules. Larrey differs, however, from Garrigues, in forbidding amputation higher than the level of the tuberosity of the tibia, the thick portion of which may be sawn, but not above the insertion of the tendon of the patella. A transverse line, drawn from this point, usually passes below the articulation of the fibula, and over the lower portion of the uppermost part of the condyles of the tibia; but, as the relative positions of the heads of the two bones to each other differ somewhat in different individuals, Larrey makes the tuberosity of the tibia the point above which the bone should never be sawn. By cutting higher, the ligament of the patella is separated from its insertion; the bursa mucosa, situated underneath it, is wounded; and the ligaments at the sides of the joint are injured: whence arise retraction of the patella, effusion of the synovia, and such disease of the knee-joint as may render another amputation indispensable. By making the division on a level with the tuberosity of the tibia, the attachment of the ligament of the patella is preserved as well as that of the flexor tendons of the leg, which are requisite for the motion of the stump. The bursa mucosa is left untouched; and the head of the bone is sawn low enough to avoid creating a risk of caries. But, says Larrey, if this mode of amputating below the knee be compared with amputation of the thigh, as recommended by authors for the cases in which the new method is proposed, the advantages of the latter are considerable. In the first place, life is less endangered, because a smaller portion of the body is removed. The operation is as easy in one situation as the other. The stumps heal with equal facility. Larrey has never seen the spongy part of the tibia become carious, nor preceptibly exfoliate. When the remaining portion of the fibula is very short, as usually happens, he recommends it to be taken away, as it is a useless body, inconvenient for the employment of a wooden leg. He directs as much skin as possible to be preserved, and a perpendicular incision, through that part of it which covers the tibia, in order to hinder the bone from making its way through it by ulceration. As M. Malgaigne particularly remarks, the exact situation of the tuberosity of the tibia should always be precisely ascertained before the operation is begun, so as to avoid cutting through the insertion of the ligament of the patella, and opening the synovial membrane behind it. The tibial tuberosity presents a triangular surface, the inferior angle of which is continuous with the crista of the tibia. As the ligament of the patella is inserted into the whole of the triangular surface, Malgaigne sanctions, where circumstances call for it, a bold division of it nearly as high as its base, the remaining connection of the patella with the tibia by the latter part

being sufficient. I fear this plan would too often be followed by injuries and disease of the knee-joint, to merit adoption.

With a stump thus formed, comprising the knee and one or two finger-breadths of the leg, the patient has a firm point of support, on which he can securely walk without a stick. The stump admits also of an artificial leg of the natural shape being worn, the knee being always bent, provided the length of the stump do not exceed the diameter of the calf of the artificial limb. (*Mém. de Chir. Mil.* t. iii. p. 386—394.) From a passage quoted by Mr. Guthrie, it would seem that Mr. Bromfield (*Chir. Obs. and Cases*, vol. i. p. 185) advised amputating as near to the knee as could be done without risk of cutting the ligament of the patella, so that the stump might not extend beyond the wooden leg. On the whole, Mr. Guthrie's own observations are favourable to this practice; but he candidly acknowledges his belief, that "it would not succeed when indiscriminately done in the hospitals of large cities," though it may frequently be practised in the army with advantage, provided the surgeon saw through the tibia below its tuberosity. (*On Gunshot Wounds*, p. 223 and 227.) Upon looking over the details of the cases recorded by Larrey in confirmation of the above statement, I was struck with one important fact, which does not justify a part of his commendations; viz. that most of the stumps were above four months in healing; and that which healed most quickly was not well before the sixty-eighth day. (See *Mém. de Chir. Mil.* t. iii. p. 57, 397, 398, &c.) Hence, unless it be supposed that the wounds produced by amputation below the knee in the ordinary manner are generally thus long in healing, as treated by the French surgeons, the inference is rather unfavourable to the method so highly commended by Larrey.

One advantage of this operation is, that frequently only the popliteal artery requires a ligature, this vessel not dividing till lower down. Before adjusting the flaps, Mr. Liston sometimes cuts off the sharp anterior edge of the tibia with the pliers, for the purpose of preventing it from injuring the integuments. Mr. Liston objects to Larrey's method of cutting away the head of the fibula, because, in several cases where he tried it, a discharge of synovial fluid occurred on the second day, followed by profuse long-continued suppuration. In more than one case, the joint became ankylosed, and one patient died from the copiousness of the discharge. Mr. Liston found, from repeated examination of the parts on the dead subject, that in cutting out the head of the fibula, the capsular ligament was wounded, or the bursal cavity beneath the popliteus muscle, communicating with that of the knee-joint. (*Elements*, part iii. p. 391—393.) [Amputation about an inch below the tuberosity of the tibia has lately been advocated by Mr. Syme. He thinks the stump thus formed is long enough to preserve the use of the knee-joint, and he prefers it because the medullary cavity is not opened, and the dense bone which is liable to exfoliation is not cut through. Like Mr. Liston, he thinks it better to retain the head of the fibula, both because its removal might give rise to inflammation in the joint, and also because it destroys the insertion of the biceps muscle. (See *Lancet*, Feb. 24, 1855.) The preservation of the flexor muscle is important, if the patient is to

walk on the ordinary wooden pin with his knee bent, as the insertion of the extensors through the medium of the ligamentum patellæ remains intact. If the head of the fibula is left, the two most important flexors, viz. the biceps on the outside and the semi-membranosus on the inside will still remain entire.

This amputation should be performed only when the state of the limb really requires its removal at so high a level. In such a case it might be preferred to the alternative of amputation through the lower third of the thigh or through the knee-joint, but it should not be selected as a matter of choice, and in preference to the amputation lower down, as it appears to have been by some of the surgeons whose observations have been quoted.]

Amputation below the Place of Election.—By some surgeons of repute, the plan of amputating through the calf of the leg, when the foot or ankle is the part diseased or injured, has been condemned. It was strongly disapproved of by Solingen, towards the close of the sixteenth century. His precept was, that the leg, like the forearm, ought to be amputated as low as possible, and the patient furnished with a suitable mechanical contrivance, on which he would be able to walk exceedingly well. Dionis was nearly in the same way of thinking upon this subject as Solingen. The opinions of these surgeons, however, had fallen into such oblivion by the middle of the seventeenth century, that Ravaton, White, and Bromfield severally imagined, that they were the first inventors of amputations low down the leg.

Mr. White, of Manchester, in a paper dated 1769 (*Med. Obs. and Inq.* vol. iv.), informs us, that he took the hint to amputate a little above the ankle, from seeing a case in which this had been done by a simple incision, with such success that the patient could walk extremely well, though with a machine that was very badly constructed. After this, Mr. White began to operate above the ankle with the double incision; and he invented a machine much better calculated for the patient to walk upon.

In 1773, Mr. Bromfield published his *Chirurgical Cases and Obs.*, wherein he mentions his having begun, about the year 1740, to amputate above the ankle, in a case of a gangrene of the foot. The patient walked so well, with the aid of a simple machine, both along a level surface, and in going up and down stairs, that it was difficult to perceive he had lost his foot. Mr. Bromfield was persuaded, however, to give up this practice, until he learned that, in 1754, a Mr. Wright had thrice amputated in this way with success, when he again had recourse to it, without the least unpleasant consequences. (See vol. i. p. 189, &c.) Of late, the method has been revived by Vacca, Brünninghausen, and Soulera, and is sanctioned by Velpeau, where the patient is not obliged to walk a great deal, or is very desirous of not letting it be seen that he has lost any part of the limb. (See *Velpeau, Nouv. Elém.* t. i. p. 480.) Velpeau recommends cutting the skin in such a manner that the cicatrix may be situated behind and not in the centre of the stump. But, as Malgaigne observes, the delicate skin in this place would hardly be capable of bearing the pressure of the kind of short boot on which the patient would have to walk. (See *Malgaigne, Manuel de Méd. Opér.* p. 294.)

The advantage of amputating a little below the

knee, is, that the pressure in walking with a wooden leg is entirely confined to the front of the limb, the cicatrix itself not being subjected to irritation. After amputating at the ankle, the pressure in walking operates directly on the cicatrix. According to Sabatier, this last plan has been extensively tried in France, but not found to answer; the stump being incapable of bearing pressure, and not continuing healed. (*Médecine Opératoire*, t. iii. p. 377, edit. 2.) The same author refers to some instances in which the patients were obliged, under these circumstances, to undergo amputation a second time; an observation made as long ago as the time of Paré. Baron Larrey spoke of the method as an objectionable operation, not merely because some patients, as, for instance, soldiers, have not the means of providing themselves with artificial legs, but because it is almost always followed by bad symptoms, owing to the small quantity of cellular substance and flesh, and the thickness of the bone at this part of the leg, whereby cicatrization is impeded. He even made the extraordinary statement that he had seen many amputations done at this part, but nearly all the patients died of nervous fever or tetanus. (*Mém. de Chir. Mil.* t. iii. p. 394.) Mr. Liston also pronounced the operation near the ankle to be inadmissible, because a sufficiency of soft parts for the protection of the stump cannot be obtained below the calf. The place for incision, he observed, is consequently limited to two points,—either immediately below the tuberosity of the tibia, or in the bellies of the gastrocnemii. The former situation he preferred in hospital practice, and among the lower orders generally; the latter in the better classes of society, who could afford to purchase an expensive artificial support. (*Elements, &c.* part iii. p. 391.)

Mr. Alanson operated in the lower third of the leg with a posterior flap, in the following manner:—The disease was in the left leg; the patient, therefore lay upon his right side, upon a table of convenient height, so as to turn the part to be first cut fully into view. The intended line, where the knife was to pass in forming the flap, had been previously marked out with ink. A longitudinal incision was made with a common scalpel, about the middle of the side of the leg; first on the outside, then on the inside, and across the tendo Achillis: hence, the intended flap was formed, first by incisions through the skin and adipose membrane, and then completed by pushing a catlin through the muscular parts in the upper incised point, and afterwards carrying it out below, in the direction of the line already mentioned. The flap was thick, containing the whole substance of the tendo Achillis. The usual double incision was made; the retractor applied to defend the soft parts; and the bone divided, as high as possible, with the saw.

The flap was placed in contact with the naked stump, and retained there, at first, by three superficial stitches, between which adhesive plasters were used. The stump healed in a month, and the man was soon able to use an artificial leg, with which he walked remarkably well. He bore the pressure of the machine totally upon the end of the stump, and was not troubled with the least excoriation or soreness.

In the next instance, in which Mr. Alanson operated, he formed the flap by pushing a double-edged knife through the leg, and passing it down-

wards and then outwards, in a line first marked out for the direction of the knife. In this way the flap was more quickly made. The leg should be completely extended during the operation, and kept in that posture till the wound is perfectly healed.

I will next notice Mr. Hey's method. He believed that very near the ankle was not the proper place for this kind of amputation. Some cases occurring, in which, from a scrofulous habit, the stump would not heal completely, nor remain healed, Mr. Hey determined to try whether amputation in a more muscular part would not secure a complete healing, and give the patient an opportunity of resting his knee on the common wooden leg, or using a socket, as he might find it most convenient. Mr. Hey latterly preferred this method, and selected the middle of the leg as the place where the bones should be sawn through. His operation was by posterior flap, and he gave detailed instructions for regulating its exact dimensions.

Mr. Fergusson, like Mr. Hey, and for similar reasons, selects the middle of the leg whenever he has the choice of site. He thinks that a stump of sufficient length for fixing any apparatus will thus be left, while, if it should be found that the weight of the body cannot be sustained in this way, the projection, when the knee is bent, will appear so trifling that little objection can be taken to it. (*Op. Surg.* ed. 3, p. 494.)

[In selecting the most appropriate situation to amputate the leg (when the surgeon has the power of selection), it should be remembered always that the risk to the patient's life is a consideration of even greater moment than his subsequent convenience in progression, and that risk will certainly be much less in amputations near the ankle than in those through the calf of the leg, both on account of the smaller size of the wound and the smaller proportion of the limb which is taken away. M. Velpeau states the proportion of deaths after amputation at the usual place of election to be as one to four or five, while in amputation near the ankle it is only about one in ten. The diminution in risk, then, is a very weighty argument in favour of the amputation low down. But, in addition to this, the only valid objection to the lower operation, namely, that the end of the stump is incapable of bearing pressure, has been removed by the greater perfection which has been attained in the adaptation of artificial limbs; since in no case, if they are properly constructed, is the pressure made to fall on this part, but is distributed equally over the rest of the limb. Mr. F. Gray, who has had great experience in the construction of artificial limbs, and has introduced many valuable improvements in their mechanism, says that "in no instance, except in Syme's and Chopart's operations, can any pressure be taken on the end or point of the stump, which is exquisitely sensitive and tender," and he takes "especial care that nothing whatever shall come in contact with it."

Mr. Gray considers that the best place for amputation, so far as the mechanical adaptation is concerned, is at the upper part of the lower third of the leg. This leaves the patient a complete command over the artificial limb, without being so long as to interfere with its mechanical arrangements. (*See Automatic Mechanism*, by F. Gray, p. 85.)

If, then, we take into consideration the twofold recommendation of the diminution of risk and the subsequent advantages to the patient, there can be little doubt that the real place of election is in the lower third of the limb, and that the calf of the leg should only be selected in exceptional cases where the expense of an artificial limb would be a continual burden to the patient; and not even then unless it appear probable that his state of health and constitution will carry him safely through the more severe operation.

Mr. Quain observes, it may be that the shorter stump is more convenient to the poor man because it will fit better the supporting ledge of the common pin leg with which he is obliged to be content afterwards. He believes, however, the superior convenience in this respect to be outweighed by the greater risk attending the larger wound. But in the case of all those who can afford the expense of the better constructed artificial limb, he thinks the lower amputation is beyond all question the more advantageous one for the facility of progression. (*See Med. Times*, Dec. 1851, p. 659.) M. Bourguéry, in comparing the amputation at the old place of election with that near the malleoli, says that both statistics and authority are in favour of the lower operation. Many surgeons whom he quotes, and "others whom it would be too long to enumerate, both in France and in other countries, are so convinced of its superiority, that they would prefer it even if no convenient artificial support could be obtained." (*See Méd. Opér.* tom. i. p. 246.)

In the lower third of the leg, as in the upper, the circular method, or that with a posterior flap, may be adopted; but it will not be necessary again to describe either operation in detail. That by posterior flap is objectionable on account of the flap being composed almost entirely of the tendo Achillis. Perhaps the most convenient mode of operating is by two semicircular flaps composed of the integuments only. These flaps may be formed either from the antero-posterior, or from the lateral surfaces of the limb. They should of course be made, not by transfixion, but by incision from without inwards. After they have been dissected up and reflected, the muscles should be divided opposite to their base by a circular incision. In the ordinary circular operation there is sometimes a difficulty in turning up the skin, in consequence of the increasing size of the limb from below upwards at this part. This difficulty is avoided by dividing the integuments in the way suggested above. When the amputation is done very near the ankle there is no interosseous space through which the knife can be passed: the retractor therefore need only have one slit, instead of two as in operating higher up.]

[AMPUTATION AT THE KNEE-JOINT.]

[Amputation through this joint was performed nearly three centuries ago by Fabricius Hildanus (1581), after which period it appears to have fallen into disuse till about 1764, when it was practised with considerable success by Hoin of Dijon, and advocated by J. L. Petit, and afterwards by Brasdor. Subsequently to this, although it was performed occasionally, it may be said to have been proscribed by the general opinion of surgeons till reintroduced by M. Velpeau in 1830. M. Velpeau collected the records of fourteen cases, out of which he found that only one had terminated fatally, and judging from these very favourable

results, he was induced to advocate amputation at the knee as preferable even to amputation through the upper part of the leg. Subsequent experience, however, has shown that such an average is by far too favourable, and M. Velpeau himself admits that he may have exaggerated the safety of the operation when he attempted to revive it in 1830. He does not now think it should ever be undertaken when it is possible to amputate lower down, though he still strongly recommends it as preferable to amputation in the lower third of the thigh. M. Malgaigne thinks it is an operation that has been too lightly condemned, and which, when the surgeon has the choice, merits a decided preference over amputation in the continuity of the thigh. (*Méd. Opér.* p. 316, ed. 5.)

The mode of operating originally adopted by Hoin, was with a posterior flap cut from the calf of the leg. He made a horizontal incision below the patella extending round the limb for three-fourths of its circumference. This incision divided the skin, ligaments, and other fibrous tissues. The leg being a little flexed, the crucial ligaments and any remaining portion of the lateral ligaments were divided with the point of the knife, after which, the leg being further flexed, and the head of the tibia drawn towards the operator, the blade of the knife was carried through the joint, and a flap was cut from the muscles of the calf long enough to cover the articular end of the femur. By this proceeding the patella was preserved. (See *Bourgéry, Méd. Opér.* t. ii. p. 269.)

M. Velpeau disapproves of the above method, and recommends a *circular* incision through the skin, three or four finger-breadths below the patella, without involving the muscles. The skin is to be dissected up and reflected, care being taken to preserve as much as possible of the cellular and adipose textures. He then divides the ligamentum patellæ and lateral ligaments; after which, bending the knee, he cuts the crucial ligaments, carries his knife through the joint, and finishes by dividing horizontally the vessels, nerves, and muscles at the posterior part on a level with the raised up integuments. (*Nouv. Elém. de Méd. Opér.* t. iii. p. 254.)

In 1836, M. Baudens operated successfully at the knee-joint in two cases of gunshot wound of the leg, and since that period he has always strongly advocated the operation. He recommends an *oval or elliptical* instead of a circular incision, with a view to retain more integument anteriorly, and throw the cicatrix more towards the posterior part. The incision should descend anteriorly five finger-breadths below the inferior border of the patella, but only three finger-breadths below this level posteriorly or towards the popliteal space. The integument is to be dissected from the front and sides of the joint, as high as the lower border of the patella, and reflected back, but posteriorly the cellular adhesions which unite the skin to the muscles should be preserved uninjured. The ligaments should next be divided in succession until the tibia is completely disarticulated. This will permit an assistant to pass his fingers into the wound and compress the popliteal artery, and the knife may be carried through the muscles at the back of the joint, so as to divide them at the level of the incision already made in the skin. In M. Baudens' first case, the skin was dissected back as high as the upper border of the patella, and

that bone was removed. A portion of the condyles of the femur, in which the ball was found to be lodged, was also removed. In the second case, the patella was retained, and the articular cartilage on it and on the lower end of the femur was not interfered with. No exfoliation of this structure took place, and the wound was completely healed in ten days. (See *Baudens, Cliniques des Plaies d'Armes à Feu*, p. 532, Paris, 1836.)

In 1824, Dr. Nathan Smith, of Connecticut, amputated successfully at the knee-joint, with *anterior and posterior flaps* of equal size. This was the first instance in which the operation was performed in America. It was some years before the date of M. Velpeau's Memoirs, and was one of the fourteen cases to which he referred. Dr. Smith's instructions for the operation are as follows:—"Mark two points, one on the out, and the other on the inside of the limb; the latter half an inch below the head of the tibia, and the other opposite to it. Then draw a semicircular line from one point to the other over the anterior part of the leg, and in such a direction that its lower part shall touch the lower part of the tubercle on the tibia into which the ligament of the patella is inserted, and then mark another circle on the posterior part of the leg exactly corresponding to the former. The above lines limit the two flaps, the former of which will be formed of the patella and its ligaments, and the latter of the head of the gastrocnemius, the tendons of the flexor muscles, and the popliteal blood-vessels and nerves. The operator should first raise the anterior flap with the patella, which will expose the anterior part of the joint and render the division of the lateral ligaments easy. Two or three strokes of the knife will then complete the section of the crucial ligaments and of the lower flap." (See *Amer. Med. Rev.* vol. ii. p. 370; and *S. Smith on Amp. at the Knee-joint*, *N. Y. Journ. of Med.* vol. ix. p. 313, 1852.) The American surgeons who have since performed the operation have usually made the anterior flap longer and the posterior flap shorter than Dr. Smith recommended, in order to throw the cicatrix well back towards the popliteal space, and out of the way of pressure from the wooden leg.

Dr. Markoe, of New York, in a paper recently published, strongly recommends amputation at the knee-joint in preference to the lower third of the thigh. Dr. Markoe has himself operated twice successfully, and has watched with care the progress of all the cases (nine in number) which have occurred in the New York Hospital. He says he first became an advocate for it in 1841, "on examining, at the New York Hospital, a stump left after this operation. The integument covering the condyles was sound, and free from callosities, excoriations, or tenderness; and with this surface applied upon a cushion in an ordinary wooden leg, he could walk without inconvenience ten miles a day, and had been able to do so since the stump was healed, some years before." He says the impression made upon his mind, when comparing it with the useless tender pointed cones of flesh left by the ordinary amputation through the thigh, was a desire to ascertain whether such an inestimable advantage might not in certain cases with safety and propriety be secured. Dr. Markoe gives the statistics of eighteen cases operated on by American surgeons, and to these he

adds twenty-eight others, occurring in Europe and collected by Dr. Stephen Smith, making forty-six cases in all. Of the American cases five, and of the European twelve, were fatal; making a total mortality of seventeen, or thirty-seven per cent. Of the different modes of operating, Dr. Markoe gives a "decided preference to that by the long anterior and short posterior flap. This has the advantage of throwing the wound on the most depending aspect of the stump, allowing easy exit to the discharges, and it moreover brings the cicatrix so far back between the condyles that it is not exposed to pressure." "There is, it is true, nothing but integument on the face of the stump, but that integument is applied over a large, smooth, natural surface, well adapted to receive and sustain pressure." (See *New York Journal of Med.* vol. xvi. 1856.)

In this country, disarticulation of the knee-joint has been very rarely practised. Mr. Syme, Mr. Fergusson, and others, have, it is true, of late years amputated occasionally through the condyles of the femur, in cases of disease of the knee-joint; but these are not, strictly speaking, disarticulations of the knee. These cases will be again referred to.

The writer is informed by Mr. Blenkins, of the Grenadier Guards, that seven amputations at the knee were performed by British surgeons in the Crimea, and that of these four died and three recovered. It is stated by Dr. G. B. Macleod, that in four of these the articular end of the femur was removed. These four, therefore, should rather be considered as examples of the operation suggested by Mr. Syme, than true disarticulations of the knee. (See *Ed. Month. Journ.* July, 1856, p. 33.)

The following are the particulars of one of the three successful cases. In this case Mr. Blenkins was the operator. At the assault on the Redan, September 8, 1855, a soldier, aged 22, received a severe compound fracture of both bones of the leg, with extensive laceration of the integuments. The state of the limb did not admit of amputation of the leg; it was therefore removed at the knee-joint, by the large anterior and small posterior flap operation, the anterior flap being made six inches in length. The patella was retained, and the cartilage on it and on the condyles of the femur was not interfered with. The posterior flap was cut from without inwards, so as to remove as much as possible of the mass of muscles of the calf, which is left in the usual mode of cutting from within outwards. The flaps came together perfectly, and the wound healed in an unusually favourable manner. In three weeks it had all but closed, and at the end of six weeks it was perfectly sound and cicatrized in every part. The end of the stump was beautifully rounded, and formed an excellent surface to receive the pressure of a wooden leg. Mr. Blenkins much prefers the operation with the long anterior flap, and he believes the mortality might not have been so great had this mode of proceeding been adopted in all the cases.

In the French army in the Crimea, M. Baudens made amputation at the knee-joint one of the subjects to which he paid special attention. He says that the opinion of all the principal surgeons engaged was that disarticulation of the knee should be preferred to amputation of the thigh in all cases where it is impossible to amputate through the

upper part of the leg. This opinion is confirmed, he adds, "by all that he has seen in his hospital experience from Marseilles and Toulon to Constantinople and the Crimea. It is in fact incontestable that disarticulation of the knee has succeeded in a given number of cases more often than amputation of the thigh, even in its inferior third." According to M. Baudens, however, amputation at the knee should be preferred to that of the thigh, only on the express condition that it should be performed immediately; consecutively he thinks amputation of the thigh should have the choice. The operation practised was invariably that recommended by M. Baudens, and by which the principal covering is obtained from the anterior part. (See *Comptes Rendus*, tom. xii. 1855, p. 1077.)

The present Editor has recently (October 1857) performed this operation at St. Mary's Hospital, on a boy eight years of age, who laboured under necrosis of the shaft of the tibia and of its upper epiphysis. An anterior flap was formed from the integument covering the lateral and anterior part of the upper third of the leg. This flap, which was of sufficient width and length to cover the condyles of the femur, was reflected upwards; the ligamentum patellæ was cut through and the joint opened. It was found that the disease had extended into the joint, but lymph had been thrown out and plastic adhesions formed, so as completely to separate it into an upper and lower compartment. In the upper compartment were situated the patella and condyles of the femur free from disease. In the lower compartment was found the head of the tibia, denuded of cartilage, bathed in pus and partially necrosed. The adhesions and ligaments were now divided; the knife carried through the joint, and a short posterior flap formed. The flaps were adjusted by interrupted sutures and light dressings applied. The line of approximation of the flaps was completely behind the condyles of the femur. Union by the first intention took place except in the neighbourhood of the ligatures. These separated in the first fortnight. A few drops of synovia were on two or three occasions seen to ooze from the wound. In a month the stump was soundly healed, and the little patient was exhibited to the members of the Western Medical Society about five weeks from the performance of the operation. At the present date, three months after the operation, the patella and anterior flap remain moveable on the condyles of the femur, and the weight of the body is borne without inconvenience on the end of the stump. Mr. Hussey also has lately amputated the leg at the knee-joint, in the Radcliffe Infirmary, Oxford, for necrosis of the tibia with immense hypertrophy of the integument and soft parts, in a lad aged 17. The operation was done with a scalpel, but the mode of proceeding is not stated. The condyles of the femur were not touched; the articular and semilunar cartilages were healthy. The amputated limb weighed 11½ pounds. The last ligatures came away on the thirteenth day, and the patient was rapidly regaining health. (See *Med. Times and Gaz.* Dec. 12, 1857, p. 604.)

Amputation at the knee-joint, although recommended by many surgeons of note in America and on the Continent, has been very rarely practised in this country. Mr. Fergusson stated in 1846, that it had never, to his knowledge, been performed; and, in fact, with the exception of the Crimean cases, the two cases by Mr. Lane and

Mr. Hussey above related, and another alluded to by Mr. Fenwick, as having occurred in the Glasgow Infirmary (see *Ed. Month. Journ.* Oct. 1847, p. 248), appear to be the only recorded instances. Many surgeons hesitate to perform it, knowing the dangerous consequences of wounds of the knee-joint, and fearful of similar results from its exposure in amputation. Indeed, although the two cases are not exactly similar, experience shows that there is ground for apprehension on this score; M. Velpeau lost three cases from purulent inflammation "in the large and deep synovial cul-de-sac which is prolonged upon the sides of the condyles and upon the anterior surface of the femur;" the suppuration from which extended upwards amongst the muscles of the thigh; and he refers to four other cases which proved fatal from the same cause. The American surgeons however, have been more fortunate in this respect. Dr. Stephen Smith says:—"Fearful as are the results of the inflammatory process instantly lighted up in ordinary wounds of the knee-joint, dangerous consequences from this source are rare exceptions in the severer wound of the bisection of this articulation in amputation." (*On Amp. of the Knee-joint, N.Y. Journ. of Med.* Nov. 1852, p. 325.)

Admitting this danger, however, there appears to be sufficient evidence to establish the expediency of the operation in suitable cases, whether of injury or disease. The mortality appears to be certainly *not greater* than after amputation of the thigh. According to the statistics given by Dr. Markoe, the mortality in the two cases is 37 per cent. as compared with 43½; the advantage being thus 6½ per cent. in favour of amputation at the knee.

But even if the mortality were *equal* in the two cases, amputation at the knee deserves preference on account of the very decided advantage which it affords the patient for progression. There is ample evidence that the stump is capable of supporting the weight of the body without pain or inconvenience; and the extent of surface and rounded form of the condyles admirably adapt it for this purpose. From the power of supporting pressure results the further advantage, alluded to by Velpeau, that the free play of the hip-joint is preserved; whereas after amputation of the thigh, the artificial limb has to take its bearings from the pelvis, and the patient walks as if he had an ankylosis of the hip-joint, all his motions being made by the pelvis, and not at the coxo-femoral articulation.

In comparing the results of different modes of operating it will be found, that the cases which have been attended with the most striking success have unquestionably been those in which the principal covering has been obtained from the anterior aspect of the joint. This object may be attained either by the elliptical incision of M. Baudens or by the large anterior and short posterior flap recommended by the American surgeons, and adopted in Mr. Lane's and Mr. Blenkins's cases. These methods are preferable to Mr. Velpeau's circular incision, because they remove the cicatrix to a position where it will not suffer irritation from pressure, and they possess several important advantages over the large posterior flap, which was recommended by Hoin. The integument in front of the knee is much better organized for bearing pressure than that of the calf; it is, in fact, the

very same which is found to bear the weight of the body so well in the kneeling position and after amputation below the knee. The flap falls at once of its own accord over the end of the bone; the position of the wound is depending and allows the discharge to escape without difficulty; the main artery is cut through before its division, and fewer ligatures will be required. The flap from the calf, on the contrary, cannot be adapted without bending it at an angle which is unnatural to it, and it tends by its own weight to fall away from the end of the bone; the wound is not so advantageously placed and many more arteries will require to be ligatured.

The patella when sound should always be retained; it affords a fixed point for the action of the extensor muscles, and these muscles will retract it sufficiently to prevent its interfering with the rounded form of the stump, while its removal would increase materially the surface of the wound.

When the cartilage on the femur is healthy, it should not be interfered with. Its presence does not impede the immediate union of the wound, whereas, by sawing off a slice of the bone an injured surface is substituted for a healthy one, with an additional risk of suppurative phlebitis from exposure of the veins in the cancellated texture; besides which, the rounded form of the condyles, which is one of the leading advantages of the operation, is thereby destroyed. M. Velpeau believes that adhesion always takes place between the flap and the cartilaginous surface, even in those cases where the wound unites by the first intention, and where no undue inflammation is excited. This adhesion, however, is not the invariable rule, for in Mr. Lane's case the patella and the flap remained distinctly moveable on the condyles beneath. When the wound does not unite by the first intention, and suppuration ensues, the cartilage will either exfoliate in fragments from the surface of the bone beneath, or it will undergo gradual disintegration, and be removed with the discharge, and the granulations from the bone will then coalesce with the granulations on the flap. (See REMARKS ON AMPUTATION AT THE JOINTS, *ante*, p. 71.)

Amputation through the Condyles of the Femur.—In 1845 Mr. Syme published a paper advocating amputation at the knee, or more correctly speaking, through the condyles of the femur, by which method he had operated successfully in two cases of diseased knee-joint. His principal reason for so doing, in preference to amputating the thigh in its lower third, was his belief that division of the cancellated texture of a bone is not so likely to be followed by inflammation of the medullary membrane and exfoliation as when the dense substance of the shaft is sawn through. Mr. Syme does not consider the state of the soft parts, usually met with in diseased joints, a sufficient reason for operating higher up, since, "however much they may be altered by scrofulous degeneration or suppuration, they readily admit of restoration to their natural condition," as is clearly shown by the results of excision of joints. In his first case, Mr. Syme "made an incision across the knee in a line with the upper edge of the patella, then pushed the knife from one side to the other under the joint, cut a flap from the calf of the leg, and finally sawed through the condyles of the thigh bone, which were ulcerated and carious." Finding he had not quite sufficient covering in this way, he made, in his second case, "the anterior semilunar

incision in a line with the *lower* edge of the patella, and had the integuments retracted before cutting into the joint above this bone." "The posterior flap must be made very long, indeed to the full extent of the gastrocnemius muscles; care being taken, however, to avoid preserving more than a moderate portion in regard to thickness." (See *Ed. M. Journ. of Med. Science*, May, 1845, p. 537.)

In the following year, however, Mr. Syme says: "As the soft parts required to form the stump in this situation are apt to be so deranged in their texture as to delay, though not prevent recovery, and thus in some measure counterbalance the advantage of exposing cancellated instead of dense bone, together with the contents of its medullary cavity, I do not persist in advocating amputation at the knee now, when satisfied that the operation by circular incision, if performed with due care and on proper principles, may be employed in the lower third of the thigh safely and advantageously. (See *Ed. M. Journ.* Nov. 1846, p. 225.)

In the same year, Mr. Fergusson performed a similar operation successfully in a case of diseased knee-joint. His mode of proceeding was, like Mr. Syme's, with a posterior flap; both are, in fact, equivalent to the original operation of Hoin, excepting as regards the removal of the patella and of part of the femoral condyles. Mr. Fergusson has seen this patient repeatedly since. He has frequently walked forty miles in a day with a very indifferently-made artificial leg; and once accomplished 120 miles in three days without the slightest damage to the tissues! (*Op. Surg.* ed. 3, p. 503.) Mr. Fergusson says he has since frequently performed this operation; but does not state how often. (*Med. Times and Gaz.* July 8, 1854, p. 26.) Mr. Jones, of Jersey, operated in 1853 in the same manner, and the result to the patient was a "most serviceable stump, upon which he could bear the weight of his trunk in progression." (*Med. Times and Gaz.* June, 1854, p. 570.) This was a secondary amputation after compound fracture of the leg. A similar practice has been followed successfully by Mr. Potter, of Newcastle. (See *Lancet*, May 27, 1854.) And also by Dr. Markoe. (See *N. Y. Journ. of Med.* Nov. 1856, p. 823.)

This operation may be substituted with advantage for amputation in the lower third of the thigh in some cases of diseased knee-joint, and also of compound fracture into the joint, from gunshot wounds, for example, when the condyles of the femur are only to a slight extent implicated. In either of these cases the removal of the lower end of the bone of course becomes a matter not of choice but of necessity. This kind of operation, however, is not likely to be very frequently required; diseased knee-joints, which are not eligible for excision of the ends of the bones, will most probably be in a condition to compel the amputation to be performed higher up; and the same may be said, as a general rule, of compound fractures in which the lower end of the femur is involved. When the end of the femur is sawn through, the operation with the posterior flap, as recommended by Hoin, may perhaps be found the best; the thick muscular cushion thus obtained will be less likely to suffer injury from the sharp edges of the sawn bone than an anterior flap, which must necessarily be composed of integument only. The large size of the flap, however, and, in diseased joints, its altered and deranged condition will probably, as

Mr. Syme found, cause delay in the healing process; but when this disadvantage has been surmounted, the condition of the stump, in the cases recorded, appears to have been in every respect highly satisfactory.]

AMPUTATION OF THE THIGH.

[Here, as in the arm, there is but one bone, and here, in like manner, the deep muscles are adherent to the bone, while the superficial ones pass from the pelvis to the leg without taking any attachment to this segment of the limb. There is no "*place of election*" for the performance of amputation of the thigh; but the rule of operating as far as possible from the trunk of the body should be invariably followed. By so doing, not only will the danger from the immediate shock of the operation be diminished, and the recovery be more rapid on account of the smaller extent of the wounded surface; but the subsequent utility of the stump, from the power which the greater leverage thus obtained will enable it to exercise over the movements of the artificial limb, will be greatly increased. The propriety of this rule is now universally admitted, both by the surgeon, whose more immediate concern is in the recovery of the patient from the operation, and also by the mechanic, who is engaged afterwards in the adaptation of the artificial limb.]

Many writers, however, have disapproved of amputating too close to the knee (*Graefe*, op. cit. p. 60); Mr. Liston recommended that the bone should not be sawn very much lower than its middle, his opinion being that "a long stump here is equally inconvenient to a person in any walk of life" (*Pract. Surg.* p. 382, ed. 4); and Langenbeck urged one objection to it, not specified by any other author, viz. that if the operation be done lower down than two hands' breadths above the knee, the femoral artery shrinks into the aponeurotic sheath which it here receives from the vastus internus and triceps, and cannot be drawn out with the forceps, so as to be separately tied, without first slitting up that sheath. Hence he recommended cutting through the muscles at the distance above the knee already mentioned. (*Bibl. für die Chir.* b. i. p. 571, 12mo. Gott. 1806.) But when I come to look at the breadth of two adult hands, and see how much of the limb would be sacrificed, at all events only to save a little trouble, I cannot bring my mind to concur with Langenbeck — the remedy being worse than the alleged evil. In general, the disease obliges the surgeon to begin the incisions two or three inches above the patella, and, as Velpeau remarks, Langenbeck's direction is superfluous. (*Nouv. Elém. de Méd. Opér.* t. i. 504.)

The patient is to be placed on a firm table, with his pelvis resting on its edge, and the limb projecting beyond it. His back should be properly supported by pillows and assistants, who are also to hold his hands, and keep him from moving too much during the operation. The ankle of the sound limb may be fastened, by means of a strong band or garter, to the nearest leg of the table.

The next thing is the application of the tourniquet. (See *TOURNIQUET*.) The pad should be placed exactly over the femoral artery, in as high a situation as can be conveniently done. When the thigh is to be amputated high up, it is better to let an assistant compress the femoral artery in

the groin with his thumb, or any commodious instrument furnished with a round blunt end, calculated for making direct pressure on the vessel without injuring the integuments. Some authors, indeed, give a general preference to this method, whether the thigh be amputated high up or low down. (*Paroisse, Opuscles de Chir.* p. 188; *Brünninghausen, Erfahr. über die Amp.* p. 273; *Langenbeck, Bibl. Chir.* p. 564; *Liston, Obs. in Ed. Med. and Surg. Journ.* vol. xx. p. 43, and *Elements*, part iii. p. 362.) Were the patient, however in a debilitated state, and unable to bear loss of blood, as there might, in this way, be considerable bleeding, by reason of the anastomoses with the branches of the internal iliac artery, I should feel disposed to employ the tourniquet whenever circumstances would conveniently admit of its application. In amputations of the thigh the great objection to the use of this instrument is, that it impedes the free and immediate retraction of the loose muscles after they have been cut; the consequence of which is, that the surgeon cannot divide so high, as he otherwise could do, the deeper muscles, which are more fixed and attached to the bone. Yet, in order to have the bone well covered with flesh, and no danger of a sugar-loaf stump, the latter object is one of vast importance. Perhaps the best general rule is, to abandon the application of the tourniquet in amputations performed as high as the middle of the thigh, except where the patient is remarkably weak, so that he cannot bear the smallest loss of blood, and no steady, intelligent assistant is at hand, to whom the compression of the artery in the groin can be prudently confided.

Mr. Guthrie, in speaking of amputations on the two lower thirds of the thigh, observes, that "in these cases the tourniquet should be used;" but in operations high up the thigh, he joins all other surgeons in recommending the inguinal artery to be compressed against the os pubis. (*On Gunshot Wounds*, p. 202.) The utility of slackening the tourniquet completely, however, as soon as the principal vessels are secured, — a piece of advice delivered by this excellent surgeon, — I presume, cannot be right on the ground which he specifies, viz. the impediment made by the strap of the instrument to the retraction of the muscles, and the consequent difficulty, in high operations, of sawing the bone, *because in common practice the bone is always sawn before any of the vessels are secured*; and loosening the tourniquet entirely, while any arterial branches still require the ligature, must generally be objectionable, if loss of blood be a disadvantage. In flap amputations, high up the limb, indeed, where the arteries are sometimes tied, before the division of the bone, the employment of a tourniquet at all is quite out of the question.

Circular Amputation of the Thigh. — Whether the right or left thigh is to be removed, it is customary, in England, for the operator to stand on the patient's right side. In France, the surgeon places himself on the outer side for either limb, which plan, when the left limb is to be removed, leaves the duty of drawing up the skin and muscles entirely to the assistant. (*Velpeau, Nouv. Elém.* 8vo. t. i. p. 507.) The great advantage of the other method seems to be, that the surgeon's left hand can be thus more conveniently and quickly brought into use than if he were always to stand on the same side as the limb he is

about to amputate. This seems to be the only assignable reason for this habit; for, when the left thigh is to be amputated, it is certainly some inconvenience to have the right limb between the operator and the one that is to be removed. But this is found less disadvantageous than not having the left hand next the wound.

An assistant, firmly grasping the thigh with both hands, is to draw up the skin and muscles, while the surgeon, beginning with that part of the edge of the knife which is towards the handle, makes a circular incision, as quickly as possible, through the integuments down to the fascia, or, as Mr. Guthrie and Dr. Hennen recommend, even completely through it. According to Mr. Guthrie, the skin cannot be sufficiently retracted, unless the fascia be divided, which he appears to think ought rather to be drawn up with the integuments than dissected from them. (*On Gunshot Wounds*, p. 204—208; also *Hennen's Military Surgery*, p. 263.) In this way, the necessity for all painful detachment of the skin from the fascia is superseded. However, in secondary amputations of the thigh, if the integuments are unsound, and cannot be retracted, Mr. Guthrie approves of their being dissected back. On the contrary, Langenbeck is very particular in enjoining surgeons to avoid cutting through the fascia by the first sweep of the knife, because he finds that the muscles are better held together, and can be more regularly divided, by cutting them and the fascia at the same time. (*Bibl. für die Chir.* b. i. p. 564.) Nor does M. Roux divide the fascia by the first incision. (*Mém. sur la Réunion immédiate de la Plaie après l'Amputation circulaire*, p. 9, 8vo. Paris, 1814.)

In a thigh of ordinary dimensions, the first incision should be made four inches below where it is intended to saw the bone. Graefe, does not dissect the skin from the muscles at all in amputating the thigh, but takes care, after making the cutaneous incision, to have the integuments and subjacent flesh very firmly drawn up before commencing the oblique division of the muscles. This retraction he also strongly advises to be done uniformly and smoothly all around the member, lest, in dividing the muscles, any irregular projection of the skin interfere with the requisite movements of the knife. (*Normen für die Abl. grösserer Gliedmassen*, p. 103.)

In common amputations of the thigh, Roux strongly disapproved of separating the skin far from the muscles, as a circumstance highly unfavourable to the healing of the wound by adhesion. He divided only a few of the cellular bands between the integuments and fascia; and occasionally he has imitated M. Louis in cutting through the skin and superficial muscles together. (*Mém. sur la Réunion de la Plaie après l'Amputation*, &c. p. 9.)

The practice of detaching the bone from the circumjacent flesh to the extent of about an inch, after the other principal incisions are completed, as advised by Celsus and Louis, I have sometimes seen followed at Saint Bartholomew's Hospital, and have adopted it myself on other occasions, with the decided advantage of letting the bones be sawn higher up than could otherwise have been effected. Mr. Guthrie, after the incisions down to the bone, even recommends dissecting back the muscles from it "for the space of two or three inches, as the size

of the limb, or other circumstances, may require ;” but I should be reluctant to imitate the practice to this extent, though inclined to think most favourably of it within more moderate limits. If we reckon that three inches of the member lie between the first circular cut in the skin and the place where the knife arrives at the bone, and then take away two or three inches more of the femur, it is clear that, in many examples, we should be getting very high up the limb ; and if a detachment of the muscles from the bone, to the extent of two or three inches, were thus made, it would at all events be of no service, unless the bone would admit of being sawn at this great distance from the termination of the oblique division of the muscles. However, if this were truly practicable (a point which I leave for others to discuss), it would certainly be consonant to the excellent general maxim laid down by J. L. Petit, that, in amputation, as much of the bone and as little of the flesh should be taken away as possible. (See *Traité des Mal. Chir.* t. iii. p. 150.) When this final detachment of the deep muscles from the bone is adopted, particular care, as Roux observes, should be taken always to divide the thick aponeurosis connecting the triceps to the linea aspera. (*Mém. sur la Réunion de la Plaie après l’Amputation*, p. 10.)

With respect to Desault’s method of amputating the thigh by a circular incision, already mentioned, he considered turning the knife obliquely upwards quite unnecessary. His plan was to cut through the muscles, layer after layer, with the precaution of retracting the first stratum before he divided the second ; the latter was then cut through on a level with the flesh that had been previously divided and retracted, and so on down to the bone. This, says he, is the right way of forming a true hollow cone, of which the integuments, which were drawn up before the muscles were cut, form the base, from which are gradually continued the various layers of muscles, and the highest point of which is the bone itself. (*Œuvres Chir. de Desault, par Bichat*, t. ii. p. 547.)

Dupuytren objected to this last method as tedious and painful, on account of the repeated division of the same textures by it. Hence, he preferred cutting through the integuments and muscles down to the bone with a single stroke of the knife, sometimes perpendicularly, sometimes obliquely. The contraction of the muscles, and the retraction produced by the assistant, who grasped the limb above the incision, instantly caused the wound to assume a conical projecting form. At the base of this cone, close to the edge of the retracted skin and muscles, the knife was applied again, and the flesh here drawn up as soon as divided. By cutting the muscular strata in succession, as they presented themselves under those already divided, and retracted, Dupuytren was able to lay bare the bone six inches above the line of the first incision. The operation was rapidly completed, and the patient saved from all the agony resulting from the dissection of the skin from the muscles. (See *Leçons Orales de Clinique Chir. de M. le Baron Dupuytren*, t. iv. p. 297.) In this plan, however, the deep muscles attached to the bone must have been cut through more than once, if the operator really made his knife penetrate to the bone at the first stroke, as is represented. The avoidance of the tedious dissection of the skin, the saving of pain, and the abridgement of the operation, were not the only

considerations in favour of this method, for one still greater influenced Dupuytren, namely, that of not destroying the natural connections of the skin to the subjacent parts, and preserving the sources of its nutrition. Hence, he followed this plan in all circular amputations of parts of limbs, where there was only one bone. (*Op. cit.* t. iv. p. 351.)

Care is to be taken to leave the nervus saphenus major out of the noose. Its diminutive size prevents it from being readily seen ; but as it is always situated close to the sheath, and on the outer and front part of the artery in the middle third of the thigh, there ought to be no great difficulty in finding it. (*Velpeau*, *op. cit.* t. i. p. 506.)

[Mr. Syme, who had for a long period been an advocate for flap amputations, has lately expressed an opinion in favour of the circular method in the lower third of the thigh ; though at or above the middle of the bone he still thinks there can be no doubt of the propriety of the flap method. His reason for changing his opinion with reference to amputation in the lower third is the tendency to protrusion of the bone from retraction of the flaps during the healing process. The retraction is of course greater in the lower than at the upper part of the limb, on account of the greater length of muscular fibre remaining. Mr. Syme observes : “ This distressing result depends upon the vital contractility of the muscular tissue, which, continuing in operation so long as the cut surface is not prevented from yielding by the formation of new adhesions, not only lessens the mass of flesh provided for covering the bone, but gradually retracts it, together with the superjacent integuments.” (*Ed. Month. Journ.* 1846.) This is in accordance with the observation made long since by Sir A. Cooper, that “ if muscular fibres are preserved with the integuments, they will contract, and retraction of the skin covering the stump will be the result.” (*Lancet*, vol. i. 1823, p. 148.) Mr. Syme makes two semicircular flaps of skin, which he causes to be retracted to the extent of two inches, and he then divides the muscles in the ordinary way by circular incisions.

In the upper half of the thigh, the increasing size of the limb from below upwards will often render difficult the retraction or reflection of the integuments after the circular incision. This is especially the case, as M. Baudens has remarked, when the limb is swollen from inflammatory effusion. To avoid this difficulty, M. Baudens has suggested a combination of the flap and circular methods. He forms *short* external and internal flaps in the ordinary way, by transfixion, but comprising only the skin and the superficial muscular substance. The flaps, being turned back, can be readily retracted towards the hip, so as to allow the *circular division* of the remaining soft parts to be made at a sufficiently high level. M. Baudens’ operations were performed in cases of gunshot fracture of the femur, and he commenced the incisions for the flaps *below* and not *above* the line of passage of the projectile. He made the circular incision fall upon the lower end of the upper fragment of the bone, the uneven end of which he resected after the separation of the limb. He found that the perforation of the flaps, made by the passage of the ball, so far from being hurtful, were advantageous by serving as outlets for the suppuration. (See *Clin. des Plaies d’Armes à Feu*, p. 527.)

The inconvenience arising from the increasing size of the limb might be avoided also, either by making two semilunar flaps of the integument instead of dividing it circularly, or by making the usual circular division, and superadding to it a longitudinal incision upwards on each side.]

Flap Amputation of the Thigh. — Although surgeons differ on the question, whether flap amputation of the thigh ought to be preferred, as the general practice, Desault's, or rather Vermale's mode of operating, has certainly obtained the sanction of many respectable names. In Guy's Hospital, flap amputation of the thigh seems now to be mostly preferred. The operation has been for many years past adopted by my friend Mr. Vincent in St. Bartholomew's Hospital; and it is the plan which is always followed by Mr. Liston in the North London Hospital. "According to the point of removal (says he), the direction of the flap varies. If, in operating high in the limb, the flaps be made laterally, there will be imminent risk of the bone protruding through the upper part of the wound; for the patient uniformly raises the stump towards his abdomen. No antagonist muscular power is left to oppose the action of the muscles inserted into the trochanter minor, and the elevation of the stump is involuntary: it always occurs to a remarkable extent in young persons. On this account, anterior and posterior flaps are here preferable to the lateral; for then the more the stump is raised the better is the end of the bone covered, the anterior flap folding over it. Transfixion is, therefore, made horizontally, and the posterior flap should be a little longer than the anterior. But, in the lower part of the limb, lateral flaps are not only not liable to the same objection, but preferable to the anterior and posterior. In the neighbourhood of the knee-joint, the soft parts consist almost entirely of ligamentous tissue on the fore and back part, and proper cushions can be obtained only from the sides. Transfixion is therefore made perpendicularly. Thus the bone will be well covered by parts likely soon to adhere," &c. (See *Liston's Elements*, part iii. p. 394.)

By Mr. Guthrie, the flap operation is considered preferable to the circular incision at the upper part of the thigh, "as it permits the head of the bone to be removed, if found necessary; allows it to be examined and cut shorter with greater ease, and makes a much better covering afterwards." (*On Gunshot Wounds*, p. 200.)

In the flap amputation of the thigh, as originally practised by Vermale, the operator takes hold of the soft parts with his left hand, and draws them more or less away from the bone. He then introduces a long sharp-pointed knife down to the anterior surface of the femur, a few lines below the place where it is intended to apply the saw. The point is then conveyed close round the outer side of the bone, and pushed through the skin at the point of the back of the thigh exactly opposite that of its entrance. By cutting from above downwards, and from within outwards, the surgeon now forms the external flap, which should be three or four inches in length. It is to be held upwards by an assistant. The point of the knife is next brought to the front angle of the wound, and, while the soft parts are drawn inwards, it is to be carried close round the inner side of the femur, and pushed out at the posterior angle of the wound, without injuring the skin there, a second time. In this way a

second flap is formed, of the same shape and length as the first. No retractor is necessary in this mode of amputating. Velpeau prefers making the external flap first, for two reasons: first, because the soft parts being less bulky on this side, it is proper to begin with saving a sufficiency of them, so that the flap may be equal in size to the other; and, secondly, because the femoral artery is not cut till the moment when the flap is completed, and the vessel may then be instantly secured without any previous pressure being made upon it in the groin. (*Velpeau, Nouv. Elém. de Méd. Opér.* t. ii. p. 511.) Flap amputation of the thigh is varied by different operators, some making anterior and posterior flaps, and others, like Langenbeck, not transfixing the limb, but cutting down to the bone from without inwards. Transfixion seems to me to be recommended by the power which it gives the surgeon of making with rapidity a capital flap.

Flap amputation of the thigh, after the manner of Vermale, is preferred by Klein, Lisfranc, Liston, and many other modern surgeons. (See *Edinb. Med. and Surg. Journ.* vol. xiv. 36—46, &c.) Of seven cases in which Klein adopted this method, the greater number were healed in ten days, and the rest in three weeks; and this success determined him in future always to practise it. After this mode, he finds there is no danger of the muscles retracting themselves, and the end of the bone protruding, even though the patient be transported from one place to another. With respect to the occasional difficulty of taking up the obliquely-cut vessels, Klein admits this objection, but thinks that it equally applies to Alanson's method. He lays great stress on the utility of giving due support to the flaps with compresses and a roller. (See *Practische Ansichten der bedeutendsten Chirurgischen Operationen*, p. 35—38, 4to. Stuttgart, 1816.)

[Mr. Fergusson makes the posterior flap about two inches longer than the anterior, to compensate for the greater retractility of the muscles at the posterior part of the thigh. Mr. South believes the retraction of the posterior flap depends, not on the greater retraction of the muscles, but "on the position in which the limb is placed after the amputation; the hind muscles, being extended, are drawn back from the face of the stump, whilst those in front are relaxed, and have, therefore, no disposition to pull away from the stump." (Translation of *Chelius*, vol. ii. p. 909.)]

If the state of the integuments did not admit of two flaps being made, a single one might be formed on the inner or outer side, the front or the back part of the limb, according to circumstances. MM. Hello and Foulloy commonly prefer making only one flap from the anterior soft parts, a method which seems to M. Velpeau to have the advantage of more certainty, than any other plan, of preventing the protrusion of the bone, because the flap is kept over the whole extent of the wound by its own weight. Yet he is disposed to believe the circular method, when well performed, preferable to all these modifications, which he would employ only as exceptions to it. (*Nouv. Elém. de Méd. Opér.* t. i. p. 512.)

In one instance, where a ball had broken the upper third of the femur, and mortification had spread so far towards the great trochanter and buttock, that it was impossible to operate, except by the flap operation, or by taking the head of the

bone out of the joint, Klein made a broad flap six inches long at the inner and upper part of the thigh, and then he cut the soft parts straight across just below the great trochanter, so as to make this wound meet the termination of the incision, by which the inner flap was formed. This patient got perfectly well in three weeks (op. cit. p. 39); and so did another very similar case, operated upon by the same gentleman (p. 43). Where the bleeding is considerable, the femoral artery and profunda should be tied previously to sawing the bone; but, if the vessels are well commanded by the pressure, the sawing ought to be first completed.

In the middle of the thigh, Lisfranc preferred amputating with two lateral flaps; pressure was made on the femoral artery as it passed over the brim of the pelvis; and the vessel is tied immediately the inner flap is formed. Lisfranc made the flaps with a long, narrow, two-edged knife, which was introduced through the limb on each side, and then cut obliquely outward and downward with it; but I think Mr. Syme is right in recommending the knife used by Mr. Liston, and the back of which is thin and blunt, except for an inch from the point. (*Ed. Med. Surg. Journ.* vol. xiv. p. 37.) Mr. Hey likewise preferred a knife with a blunt back, lest the vessels should be cut with it in a way that would render the securing of them troublesome.

[Mr. Luke adopts the plan of cutting the first flap by transfixion, and the second from the skin towards the bone. In this way the two flaps may be made exactly equal in size, and the edge of the second may without difficulty be cut as evenly as that of the first. "The operator, whether intending to remove either the right or the left limb, stands on the right side of the patient. He places the left hand on the thigh, above the part to be operated on, then takes a profile view of the limb, and inserts the amputating knife midway between its anterior and posterior surface. It is passed quickly transversely to the opposite side of the limb, and, by being inclined neither backwards nor forwards, is made to emerge at a point corresponding to that at which the instrument was passed in. The knife is then carried downwards and forwards, so as to make the lower flap, which, in consequence of its having been formed during the tension of the integuments, is perfectly even. The upper flap is then proceeded with, and is formed in a reverse manner to the lower. The knife is swept round the integument, commencing a little anterior to the point of emergence of the knife in the first steps of the formation of the lower flap, and terminating a little in front of the point of entrance, the incision corresponding in form and length to the incision of the skin in the lower flap. Two sweeps of the knife obliquely backwards are sufficient to divide the subcutaneous muscles. The lower and upper flaps are thus made, and the operation is finished in the ordinary manner. The two flaps being thus equal in length, and having their bases equal and their borders even, can be applied easily to each other without any undue traction. On the cessation of hemorrhage, they are brought together by sutures, and supported by a compress above and below, maintained in position by a few strips of plaster, and a turn or two of a roller. The application of the compresses is a matter of considerable importance, the object in

their use being to apply a sufficient amount of support to keep the whole of the opposed surfaces of the flaps in mutual contact. With this object in view, their size should be so regulated as to be applied over the entire surface of each flap, but not on the extremity of the bone in the angle between the flaps." Mr. Luke attributes the favourable result that has attended his amputations in a great measure to the careful application of the compresses. Primary adhesion of the two flaps has frequently taken place throughout their entire extent; and, in most instances, this has been the case to a greater or lesser degree. (See *Ward*, in *Med. Times and Gaz.* Jan. 1852.)]

AMPUTATION AT THE HIP-JOINT.

The very idea of this formidable operation, for a long while checked the hand even of the most ready advocate for the use of the amputating knife, and every mind shuddered at so extensive a mutilation. Still, it could not be denied, that the chance of saving life occasionally depended upon a submission to the greatest temporary suffering, and that, without the most cruel of sacrifices, the preservation of the patient was totally impossible. Dreadful as amputation at the hip appeared, both in respect to the magnitude of the part of the body to be removed, and the extent of the wound caused by such removal, the desperate nature of some cases at length began to incline surgeons to view more dispassionately a scheme, at which the mind at first naturally revolted. Morand is the earliest practitioner who made this severe operation the subject of attention. (*Opuscles de Chir.* t. i. p. 176, 8vo.) In 1739, two essays on the same topic were communicated to the Royal Academy of Surgery at Paris, by two of his pupils, Volner and Puthod. In 1743, Ravaton wished to have performed amputation at the hip-joint for a gunshot fracture of the trochanter major and neck of the thigh-bone, but was prevented by the opposition of other surgeons. (*Chir. d'Arm.* p. 323, &c.) In 1748, the propriety of attempting the operation was urged by L'Alouette. (*Disp. Chir. Halleri*, t. v. p. 265.) At length, the Royal Academy of Surgery at Paris thought the subject highly deserving of further investigation. In 1756, they therefore proposed the following question, as the grand prize subject: *In the case, in which amputation of the hip-joint should appear to be the only resource for saving the patient's life, to determine whether this operation ought to be practised, and what would be the best way of performing it?* No satisfactory memoirs having been presented, the same subject was proposed again in 1759. The approbation of the Academy was now conferred on a paper written by Barbet, in which the propriety of amputating at the hip-joint was defended, and some of the cases demanding the operation specified. If, for instance, a cannon-ball, or any other violently contusing cause, had carried off or crushed the thigh, so as to leave only a few parts to be cut to make the separation complete, he thought a surgeon ought not to hesitate about doing it. The same author conceived that a sphacelus extending to the circumference of the joint, and destroying the greatest part of the surrounding flesh, might also render the operation equally necessary and easy. (See *Sabatier, Méd. Opér.* t. iii. p. 271, &c.) Cases were also adduced, where the surgeon completed the separation of the dead parts with a

knife. However, this cannot be considered as amputation at the hip-joint. Dividing a few dead fibres was a thing of no importance, in regard to the likelihood of its creating any bad symptoms. The proceeding, in fact, seems to me to have no analogy at all to the bloody operation of taking the thigh-bone out of the socket. It is quite a different thing, when the operator has to cut through parts which bleed profusely, and are endowed with life and sensibility. [Mr. Cooper is here probably alluding to a case mentioned in M. Barbet's essay, which was operated on in 1748, by La Croix, of Orleans. This case, however, has since been mentioned by Mr. Sands Cox, by Mr. South, and by Dr. Stephen Smith, as the first example of amputation at the hip-joint. The patient was a boy of fourteen, both of whose lower limbs had become gangrenous from eating diseased rye; the first operation was through the right thigh, and four days after the left thigh was amputated at the hip-joint; he seemed to be going on very well, but died on the eleventh day after the second operation. (*South's Chelius*, vol. ii. p. 933.) The operation seems to have consisted merely of the division of the round ligament and sciatic nerve with a pair of scissors.]

In addition to the memoir by Barbet, thirty-three other essays were offered to the Academy, the majority of which were filled with arguments in favour of the operation; and, besides these productions, two other memoirs were published at Paris, one by Goursaud in 1758, explaining a new method of operating, and another by Moublet (see *Journ. de Méd.* an. 1759).

Some of the best surgeons of the last and present century condemn the proceeding. The following are Mr. Pott's sentiments:—"M. Bili-guer and M. Tissot are the only people whom I have met with, or heard of, in the profession, who speak of an amputation in the joint of the hip as an advisable thing, or as being preferable to the same operation in the thigh." After a quotation or two, he continues—"That amputation in the joint of the hip is not an impracticable operation (although it be a dreadful one), I very well know. I cannot say that I have ever done it, *but I have seen it done*, and am now very sure I shall never do it, unless it be on a dead body. The parallel, which is drawn between this operation and that in the shoulder, will not hold. In the latter, it sometimes happens, that the caries is confined to the head of the os humeri, and that the scapula is perfectly sound and unaffected. In the case of a carious hip-joint this never is the fact; the acetabulum ischii, and parts about, are always, more or less, in the same state, or at least in a distempered one, and so indeed most frequently are the parts within the pelvis," &c. (*Pott on Amputation*.) Here it may be remarked, that Pott was right, inasmuch as the operation is totally unjustifiable in disease of the hip-joint; but wrong in not perceiving that, though unfit for such a case, it might be proper for others. Callisen had difficulty in supposing any circumstances, in which the operation could be undertaken with hopes of success. (*Syst. Chir. Hod.* p. 418, t. ii. edit. 1800.) And Richerand thinks, that, unless the limb be nearly separated by the disease, or accident, a prudent surgeon should decline making the attempt. (*Nosogr. Chir.* t. iv. p. 519, edit. 4.)

It is a remarkable fact in the history of surgery,

that an operation, which had been invented in France, and concerning which so much had been written in that country, should have been first put in practice in England. "I have been informed," (says Professor Thomson,) "that the operation was performed in London by the late Mr. H. Thomson, surgeon to the London Hospital, and imagine that it must have been his operation to which Mr. Pott alludes." (*Obs. in the Mil. Hospitals in Belgium*, p. 264.) At all events, whether this was the identical case which Mr. Pott saw, or not, the example referred to by this distinguished surgeon is the earliest instance of the operation being actually performed. [The correctness of this statement is somewhat doubtful, even if we exclude the case by La Croix in 1748 already referred to, and to which the priority has been given of late years. The date of Mr. Thomson's case is unknown, and as M. Perrault operated in France in 1773, about the period that Mr. Thomson's case is supposed to have occurred, it is impossible to decide whether the priority should be accorded to the French or the English surgeon. Mr. South, who has made inquiries on this point, says, "Whether Thomson or Perrault operated first, or whether Thomson operated before Kerr, I cannot ascertain." (*South's Chelius*, vol. ii. p. 933.)] In the first successful amputation of the hip, M. Perrault, of Sainte Maure, was the operator. It was done in the year 1773, in a case of traumatic gangrene. The particulars are recorded by Sabatier. The patient, named Goix, recovered, and afterwards lived a good while as cook at an inn at St. Maure, where M. Velpeau saw his son in 1815. (See *Velpeau, Nouv. Elém. &c.* t. i. p. 514.) In Dec. 1774, it was performed by Mr. Kerr, of Northampton, on a girl between eleven and twelve years of age, in a case of diseased hip; a case, however, in which I am completely satisfied that it ought never to be attempted, for the reason laid down by Mr. Pott. In fact, Mr. Kerr, after removing the limb, found the acetabulum, and all the adjacent parts of the ossa innominata, carious. But the experiment was here rendered still more hopeless, by the patient being consumptive. Yet, with all these disadvantages, the girl lived till the eighteenth day from the operation, and, after death, her lungs were found to be a complete mass of disease, one of them being totally reduced to matter. (See *Duncan's Med. Commentaries*, vol. vi. p. 337. 8vo. Lond. 1779.) Although amputation at the hip used commonly to be demonstrated on the dead subject, by lecturers on surgery in London, the observation of M. Velpeau is very correct, that in England and Germany little serious idea was entertained of reviving the practice of it on the living till the commencement of the present century, and that about this epoch several trials of it were made by surgeons of the French army. M. A. Blandin relates three cases. His first patient was operated upon in August, 1794, and recovered. The second also got well, and the third lived till the fifty-eighth day after the operation. About the same period, M. Perret, another military surgeon, had one successful case. In 1798, Mulder amputated at the hip with success, on a young woman aged 18. (See *Velpeau, Elém. de Méd. Opér.* t. i. p. 514.) Larrey performed this operation twice in Egypt; and once, while he was serving with the French army on the Rhine. He was encouraged to make these attempts to save his

patients by the consideration, that he had already preserved some lives by amputating either both thighs, both legs, or both arms, or removing the humerus at the shoulder-joint. Larrey has also the merit of having first done the operation in the description of cases, in which (with the exception of bad examples of necrosis, or of incurable disease, of the higher part of the femur) it is more decidedly proper than any other; viz. gunshot injuries of the head, neck, and upper part of the femur, with or without injury of the femoral artery, or where the limb has been carried away by a shell, or cannon-ball, too high up to admit of amputation in the ordinary manner. However, he also regards as fit occasions for amputation at the hip-joint, circumstances in which, from gunshot violence, the limb is seized, or threatened, with gangrene, nearly up to the hip. (*Mém. de Chir. Mil. t. ii. p. 185.*)

Severe as the operation is, Larrey contends that, if it ever prove the means of saving lives which are in danger, it is an act of humanity, and he argues that it is justifiable by the old maxim of Hippocrates, "Ad extremos morbos extrema remedia." To the chief objections which have been made to it, he replies, 1st, That the wound is more alarming than dangerous. The Cæsarean operation (says he) has been successfully performed on the living female, and is still recommended by many practitioners. L'Aumonier, principal surgeon of the Rouen Hospital, successfully removed a scirrhus ovary of considerable size. Examples are recorded of the arm and scapula being torn away, and the patients soon recovering. Besides, the surgeon has it in his power to lessen the wound produced by the operation. 2ndly, The dangers of hemorrhage may be obviated by the assistants temporarily placing their fingers on the mouths of the cut vessels, until ligatures can be applied.

In confirmation of his sentiments, concerning the propriety of the operation, Larrey adverts to a fact reported by Morand, where a soldier had both his legs amputated very high up, and also both his arms so near the shoulders, that he could hold nothing in his armpits. Yet mutilated as he was, he enjoyed good health. (*Opusculs de Chir. p. 183.*) And Larrey, in his own work, has recorded several instances, in which the whole of a limb was removed, or more than the halves of both the upper or lower extremities of the same subject, without any fatal constitutional disturbance. (*Mém. de Chir. Mil. t. ii. p. 182—184.*) One of his patients above alluded to survived the operation a week, at the end of which he was carried off by the plague; and the others died, after being conveyed, in a very uneasy manner, during a precipitate march of the army. (See *Relation de l'Expédition de l'Armée d'Orient en Egypte, &c. p. 319. 8vo. Paris, 1803.*) At the battle of Wagram, Larrey operated at the hip-joint on two soldiers of the imperial guard, under very unfavourable circumstances; these patients died in a few hours. (*Mém. de Chir. Mil. t. iii. p. 349.*)

Whatever method of amputating at the hip be adopted, the surgeon should remember, that the acetabulum is not deep enough to receive the entire head of the femur, which constitutes more than the half of a sphere, and is so embraced by the fibrous capsule, that it remains as it were strangled, if this latter part be not divided close to the margin of the acetabulum. As for the liga-

mentum teres, it is rendered tense by abduction of the limb, and presents itself to the edge of the knife. On the contrary, if the operator begin with dividing the external portion of the capsule, the limb should be placed in the position of adduction; the ligamentum teres is then relaxed, but it makes no resistance to the disarticulation, and may afterwards be easily divided. The hip-joint is more superficial in front than in any other direction. A line drawn perpendicularly downwards, from the union of the middle with the external third of Poupert's ligament, will be sure to pass over the fore part of it.

Internal and external Flaps.—Larrey operated as follows:—He began with making an incision in the track of the inguinal artery in the bend of the groin, and tied this vessel as closely as possible to Poupert's ligament, in order that the ligature, which was placed above the origin of the circumflex arteries and the profunda, might obviate all inconvenience from the bleeding, which might otherwise have happened from their numerous branches. This being done, a straight knife was perpendicularly plunged between the tendons of the muscles attached to the trochanter minor and the base of the neck of the femur, so as to bring out its point at the back part of the limb, or in a diametrically opposite situation to its first entrance; and now, by directing the knife obliquely inwards and downwards, a flap, which was not to be too large, was made of the soft parts at the inner and upper portion of the limb. This flap was now drawn towards the scrotum by an assistant, and the articulation was brought into view. The obturator artery, and some branches of the pudendal, wounded in making the flap, were immediately tied. The thigh was now put into the state of abduction; the inner part of the orbicular ligament, made tense by this position, was divided, and the joint opened. The ligamentum teres was then cut, and the bone dislocated. The knife was next brought to the outside of the great trochanter, and an external flap formed of the soft parts, calculated to meet that which had been made at the inner side of the limb. In proceeding through the operation, Larrey secured, as soon as they were divided, the obturator arteries, and several branches of the pudendal, gluteal, and ischiatic arteries. The two flaps were brought together, and kept in this position, with strips of adhesive plaster, and a woollen spica bandage. (See *Mém. de Chir. Mil. t. ii. p. 186—188.*)

In the Russian campaign, Larrey had two more opportunities of amputating at the hip-joint. In the first instance, he operated upon a Russian at Witepsk, whose thigh-bone was broken to pieces up to the trochanter, and the soft parts of two-thirds of the thickness of the limb destroyed. This man went on as favourably as possible until the 25th day from the operation, the parts being healed except at two points, where the ligatures had been brought out; but, unfortunately a scarcity of provisions now occurred, and the patient died on the 29th or 30th day. The second operation was done on a French dragoon, after the battle of Mozaïsk, who was afterwards seen perfectly cured by the surgeon-major, at Orcha, who received him there, and made a report of the fact to Larrey. (See *Mém. de Chir. Mil. t. iv. p. 26, 50, 51, 8vo. Paris, 1817.*)

In 1812, M. Baffos amputated at the hip nearly

in the manner of Larrey, except that he only compressed the artery in the groin, and did not begin with tying it, a method to which Larrey himself afterwards gave the preference. (See *Mém de Chir. Mil.* t. iv. p. 434.) The patient was only seven years old, and the case a diseased hip. The wound healed, but the child died of scrofula three months afterwards. The cotyloid cavity was found full of fungous flesh, and the os innominatum carious. As the latter state always exists in the diseased hip-joint, the whole of the disease does not admit of removal by amputation, and consequently the attempt ought never to be made. (See JOINTS, DISEASES OF.)

The plan of operation, adopted by Baffos, is considered, I believe, by all surgeons of the present day, better than that formerly practised by Larrey, inasmuch as the unnecessary preliminary measure of taking up the artery in the groin, instead of simply compressing it against the os pubis, was rejected. Cutting down to the artery as a precaution against hemorrhage is doing a double operation, and putting the patient to needless suffering: it was the earliest method, having been proposed by Volther and Puthod. Who was the first proposer to compress the artery against the os pubis, instead of cutting down to the vessel, I am not at present aware, but the plan was publicly recommended by Mr. Abernethy, in his anatomical lectures, for the last thirty years of his life.

Lisfranc was said to complete amputation at the hip-joint upon the dead subject in ten seconds; the following was his method, as described by a modern writer:—The nates of the patient resting on the edge of the table, and the limb being supported by an assistant, the operator draws a line an inch in length, from the anterior and superior spinous process of the ilium, straight down the thigh. From this point, he marks another inwards towards the pubes, of half an inch, so as to form a right angle. On the inner extremity of the last, he places the point of a long-bladed catlin, and pushes it perpendicularly downwards, till it strikes against the head of the femur. Then passing it on the outer side of the bone, he thrusts it onwards till it protrudes at about an inch from the margin of the anus. He now cuts outwards, for near an inch, in order to clear the great trochanter, and forms the external flap, four or five inches in length, by cutting down the limb between the muscles and bone. The femoral artery, which may now be seen, is compressed between the fingers and thumb of an assistant, while the operator thrusts the knife in and out at the same points, as before; but carrying it on the inner side of the head of the bone, he forms a smaller flap on that side of the extremity. Then, with the point of the knife, he cuts through the capsular ligament, dislocates the bone, and removes the limb by dividing the round ligament, &c. (See *Averill's Operative Surgery*, Lond. 1823, p. 158, &c.; *Maingault, Méd. Opératoire*, fol. Paris, 1822.) It is obvious (says Mr. Syme) that so long as the surgeon merely cuts downwards, and keeps close by the bone, he will not injure the femoral artery, which cannot be divided till the knife is carried outwards. This is one great excellence referred by Lisfranc to his operation; for, before the surgeon cuts the artery, the assistant can introduce his fingers into the wound, and compress the vessel. The disarticulation is accomplished as follows:

The surgeon, seizing the limb with his left hand while the assistant holds aside the flaps, makes a cut half round the margin of the acetabulum at its fore part. The limb is then put into the posture of abduction, the bone starts from its socket, the knife is carried round its head, and the triangular ligament, and remains of the capsular ligament, are divided. (See *Ed. Med. Surg. Jour.* No. 78, p. 41.) A similar method of operating was followed by Walther. (See *Graefe and Walther's Journ.* Also *Anderson's Quarterly Journ.* vol. i. p. 630.) It was likewise preferred by Mr. Syme, in an interesting case, where he amputated at the hip-joint for an extensive necrosis of the femur, involving the neck of the bone. Unfortunately, when the wound was nearly healed, the patient became dropsical, and died at the beginning of the eighth week from the period when his limb was taken off. (Op. cit. p. 25.) Dupuytren made a semilunar incision, with its convexity downwards; it began near the anterior superior spine of the ilium, and terminated near the tuberosity of the ischium. Only the skin was first divided, which was then retracted by an assistant, and the muscles cut in the same direction, so as to form the internal flap four or five inches long. This was reflected, the capsule opened in Larrey's manner, the knife passed through the joint, and the outer flap made. Dupuytren and Béclard preferred compressing the artery on the horizontal branch of the os pubis to applying a ligature to it. Here we find two very high authorities in support of what has always seemed to me the best practice.

Langenbeck begins the first incision on the outside of the femoral artery, and forms the external flap, by extending the wound towards the tuberosity of the ischium. The knee is then inclined inwards, and the head of the femur dislocated: after which the knife is carried to the inside of the thigh, and the inner flap made. (*Bibl. für die Chir.* b. iv. s. 512.) Béclard's method seems to differ from this, chiefly by transfixion being adopted in making the flaps. The same observation applies to Lisfranc's plan. It would be useless to describe every variety of operating where the only peculiarity consists either in making the outer or the inner flap first; or in transfixion, and then cutting from within towards the skin; or in not transfixing the limb, but cutting from the integuments inwards. Some operators also make one flap longer than the other; while others, with Delpech, consider the wound more likely to heal favourably when only an internal flap is made. (See *Velpeau, Nouv. Elém.* t. i. p. 522.)

When serving with the army in Holland in 1814, I assisted the late Dr. Cole in the performance of this operation. The plan adopted by him was that taught by Mr. Abernethy, in his lectures, for more than thirty years. The flow of blood through the femoral artery was stopped by compressing the vessel in the groin with the handle of a key covered with lint. The thigh was then amputated as high as possible, close below the trochanters. The femoral artery was immediately secured, and afterwards every other vessel requiring ligature. An incision was now made near the border of the acetabulum, the cotyloid ligament divided, and the head of the bone removed with the utmost facility and expedition. The patient lost even less blood than in an ordinary amputation, and the wound admitted of being

brought together with adhesive plaster in the best manner possible, so as to represent a transverse line. I am sorry to add, that the patient lived only till the following day. In one dreadful case of fracture of the upper part of the femur by a grape-shot, where the operation had been delayed too long, the whole limb being inundated with matter, and the upper end of the lower portion of the bone projecting through the flesh backward, I ventured to perform the same operation at Oudenbosch in Holland, a few days after the assault on Bergen-op-Zoom; and here happened what must often occur: immediately the soft parts had been divided, as the bone was broken to pieces, the limb came off, leaving the head of the bone, the trochanters, and a small piece below them projecting. Had not the man appeared in a very bad way by the time the vessels had been secured, I should now have removed the head of the bone; but the shock of the operation was such that he survived it but a few minutes, though scarcely any blood was lost. The mode of operating by the circular incision is preferred by Graefe, who unknowingly considers it as a new method. (*Normen für die Abl. grösserer Gliedm.* p. 118.) It has also been proposed by Dr. Veitch, with the modification of leaving an inch or two of the bone projecting, which is done without giving any additional pain, by dissecting off the soft parts below the first incisions down to the bone. This projecting piece is intended to serve as a lever, with which the head of the bone is to be got out of the acetabulum. (*Edin Med. and Surg. Journ.* vol. iii. p. 129.) Ingenious as this suggestion may be, I do not regard it as an important practical improvement; 1st, because in almost all cases where the operation is necessary, the bone is so fractured that its division is already made by the injury: 2ndly, because the scheme is unnecessary; for, in Dr. Cole's case, where I assisted, the head of the femur was removed from the acetabulum with the utmost facility by merely making an incision over that cavity, cutting the ligaments, and availing ourselves of the small piece of bone accidentally projecting. In fact, in all gunshot injuries requiring this operation, excepting a few instances of spreading gangrene from wounds, the bone is usually broken too high for Dr. Veitch's method to be practicable. With the same view of facilitating the exit of the head of the bone from the acetabulum, Graefe (p. 123) recommends dividing the transverse ligament which completes the brim of the anterior and inferior sides of the socket. Disarticulation will always be free from difficulty, however, if the capsule be divided close to the borders of the acetabulum.

Sir Astley Cooper commenced his operation by making an incision just below Poupert's ligament, a little on the outside of the femoral artery. The wound was then carried obliquely downwards and outwards to the back of the thigh, about one-third of the way down it, from which point the knife was carried in the opposite direction, obliquely upwards and inwards to meet the first incision, so as to form an elliptical curve. The femoral artery, being now divided, was immediately tied. The muscles were next cut through, another artery secured, and the bone taken out of its socket. Only about twelve ounces of blood were lost.

Oval incision.—The following method, recommended by M. Scoutteten, is stated not yet to

have been practised on the living subject (*Vel-peau, Nouv. Elém.* t. i. p. 525), though Sir Astley Cooper's plan seems to have been very similar to it in regard to the track of the incisions. The patient is to lie on the opposite side of the body to that on which the operation is to be done. The inguinal artery is to be compressed. The surgeon, standing behind the limb, is to put the thumb or forefinger of his left hand on the great trochanter. With the right he introduces the point of the knife perpendicularly over this process, and then gradually depressing the handle, extends the incision forwards and inwards four finger-breadths below the groin. He then carries the knife round the limb, cutting as deeply as possible and bringing the knife at length up to the point from which the wound commenced. All the muscular fibres are rarely divided by this first incision, and hence the knife must generally be applied again, ere this first stage of the operation can be completed. For the purpose of getting at the capsule, the sides of the wound must be kept apart, and any muscular fibres, not yet cut, be divided. As soon as the capsule is perceived, it is to be cut through perpendicularly on the head of the femur. The limb is now to be somewhat depressed, and the foot turned outwards, whereby the head of the bone is forced nearly out of its socket, and quits it completely as soon as the round ligament is cut, which is the only part by which it is confined. The operator then raises the thigh bone, so as to make its head project; after which he cuts the rest of the capsule and muscular fibres, and completes the separation of the limb. When the operation is on the left side, the surgeon stands in front of the limb. (See *Scoutteten, Méthode Ovale, ou Nouvelle Méthode pour amputer dans les Articulations*, Paris, 1827, 4to.) [This method has lately been adopted in five cases by Professor Heyfelder, of Erlangen, and three of the patients recovered. He considers this mode of operation affords great advantages for the apposition and cicatrization of the wound, and attributes the success he has met with, in a great measure, to its employment. (*Deutsche Klinik*, March, 1853.)]

Anterior and Posterior Flaps.—Mr. Liston preferred anterior and posterior flaps. The patient is placed on a firm table, with the nates projecting a little beyond its edge. The sound limb may be secured to the foot of the table with a towel; all occasion for an assistant to hold it being thus done away with, and more freedom afforded to the operator in his movements. The other limb is supported by one assistant, while another presses with one or both thumbs on the femoral artery, where it passes over the pubes. Transfixion is then performed horizontally, the knife passing in a somewhat semicircular direction, so as to include as much of the soft parts as possible, and an anterior flap is made by cutting downwards. During the passage of the knife across the joint, the assistant, holding the limb, rotates the limb, if it be the right one, a little outwards, or, if it be the left, in the contrary direction, so as to facilitate the bringing of the point of the knife through the skin well inwards. After the formation of the flap, the assistant abducts the limb forcibly, and depresses it; the joint is opened; the round ligament cut; the rest of the capsule divided; the blade of the knife placed behind the great trochanter; and the posterior flap quickly formed. After transfixion for the anterior flap, and when the sawing motion

of the knife has made a little advance, the compressing assistant shifts his hands into the incision immediately behind the back of the knife, and thus obtains a firm grasp of the femoral artery, previously to its division. He retains this hold during the rest of the operation, at the same time retracting the flap. As soon as the limb is off, the bleeding vessels in the posterior flap are compressed, and tied as quickly as possible. Lastly, the femoral artery is secured, which, while the assistant retains his hold of it, will not bleed. (See *Liston's Elements*, part iii. p. 395.) The methods of M. Plantade, M. Manec, and Mr. Ashmead (see *Velpeau, Nouv. Elém. &c. t. i. p. 520*) are all only modifications of the foregoing plan. M. Plantade makes the principal flap in front, and seems to have been one of the greatest advocates of this method, which he began to recommend in 1806.

Amputation at the hip-joint has now been performed in many instances, and the patients saved. The earliest example of success is that done, as I have stated, by M. Perrault in 1773. Other successful operations, done by Blandin and Mulder, I have already noticed. Another successful amputation of the hip, (the first by any British surgeon,) was performed by Mr. Brownrigg, staff surgeon, on the 12th of December, 1812. The upper part of the thigh-bone had been broken by a gunshot near Merida, in Spain, on the 29th of December, 1811. Some time ago, the man was living at Spalding in Lincolnshire in perfect health. Other successful amputations of the hip are those performed by Larrey at Witepsk; by Mr. Guthrie in the Netherlands on a French prisoner of war; and by Sir Astley Cooper, who performed the operation on account of a disease of the higher part of the femur. As the patient had formerly suffered amputation of the thigh, it was certainly not the sudden removal of nearly a quarter of him; but, I cannot presume to say, what difference in the chances of success, and whether any, would be connected with the circumstance. The same remark applies to a case lately under Mr. Mayo, where the patient, a young woman, recovered. The proceeding was adopted on account of the agony experienced by the patient from a neuralgic affection of her stump.

In June, 1824, amputation at the hip was done by Delpech, on account of a necrosis of the femur, and the patient was completely well in the following September. (See *Revue Médicale*.) The operation was also performed by Dr. Mott, of New York, on the 7th of October, 1824, and the whole of the wound had healed by the 20th of November. This case was a bad fracture of the upper part of the femur, followed by abscesses and disease of the bone. (See *Philadelphia Journal*, No. 9, vol. v. New Series.) The patient's age was favourable, as he was a boy of only ten years of age. At this period of life, the chances of success will always be greater than in adults, not only in consequence of the remedial power of nature being then particularly great, but on account of the smaller dimensions of the wound necessary for the purposes of the operation. Another successful amputation at the hip was performed by Mr. Orton in 1826; the disease commenced in the knee; but terminated in extensive disease of the thigh-bone, large abscesses, and dislocation of the knee, the leg being fixed in the bent position, and drawn under the thigh. (See *Méd. Chir.*

Trans. vol. xiii. p. 605.) The operation has also been performed with a successful result by Wedemeyer and Bryce.

On the other hand, the failures of this operation are numerous, though undertaken by surgeons of reputation and ability. Mr. Guthrie, Dr. Emery, Mr. Brownrigg, Baron Larrey, Baron Graefe, Sir B. Brodie, Mr. Carmichael (*Trans. of the Assoc. Physicians*, vol. iii.); Drs. Blick, Emery, and Cole; Baron Dupuytren; MM. Gensoul, Clot, Roux, Delpech, Pelletan, Dieffenbach, Syme, Velpeau, and Walther, have each had the mortification of losing at least one of their patients, after this very severe operation.

A calculation has been made, that the proportion of recoveries has been six in twenty operations, which is equivalent to a mortality of 70 per cent. At all events, it appears that, in the course of ten years, nearly twenty well-authenticated instances of recovery, after this severe operation, have occurred. (See *Velpeau, Nouv. Elém. de Méd. Opér. t. i. p. 515*; *Chelius, Handb. der Chir. b. ii. p. 763*.)

[In 1844, Mr. Sands Cox, of Birmingham, had a successful case, in a young woman who had previously undergone amputation of the thigh for a diseased knee-joint. The amputation at the hip was on account of a diseased growth in the stump, with obstinate fungous ulceration of the integuments. This, it should be observed, is the third instance of successful amputation at the hip where amputation of the thigh had been previously undergone; the other two, by Sir A. Cooper and Mr. Mayo, have been already mentioned. Two more have since occurred, and each with a similar result; one by Mr. Syme, in 1849, the other by Dr. Bradbury of Boston, U.S., in 1852. The reason of the great success of these cases is, no doubt, to be found in the smaller amount of shock and of disturbance to the circulation which they occasion; for although the actual operation is the same, the immediate impression on the system must be very different where some six inches only of the limb are removed, and where the whole member, equal in weight perhaps to one-fourth of the entire body, is at once taken away. In these five cases, the amputation of the thigh had been done some time previously, and the patients had either completely recovered, or, at any rate, were no longer suffering from its immediate effects. But there are two other instances of amputation of the hip following amputation of the thigh under less favourable circumstances; where, in fact, the second operation was rendered necessary by the evil consequences resulting from the first. One of these, which recovered, was by M. Textor, in 1841, for gangrene of the stump after amputation of the knee. The other, which was fatal, was by Mr. Guthrie, in 1814, for sloughing and hemorrhage after amputation of the thigh for gunshot wound. We have thus seven examples of amputation at the hip where the thigh had been previously amputated, with the remarkable result that six out of the seven were successful.]

In 1845, Mr. Cox published a Memoir on Amputation at the Hip-joint, at which period he was enabled to collect the records of eighty-four cases, which he gives in a tabular form. Of the eighty-four, twenty-six recovered, and fifty-eight died, giving a mortality of, as nearly as possible, 69 per cent. This, however, is in all probability too fa-

vourable a result, for, as Mr. Cox observes, there is "great difficulty in obtaining an account of the failures of the operation, especially of the cases which were operated on on the field of battle, where the operators had no time or opportunity to commit the details to paper;" while, on the other hand, the successful cases have always excited so much interest, that there is little likelihood that any of them have been left unrecorded.

In 1852, Dr. Stephen Smith, of New York, published a similar statement, comprising ninety-eight cases. Several successful cases had occurred in the interval since the appearance of Mr. Sands Cox's memoir, in 1845. The ratio of mortality is, therefore, very considerably reduced, and, according to Dr. Smith, the proportion of deaths to recoveries in the whole ninety-eight, is as fifty-six to forty-two, or 57.14 per cent. Some fatal cases, however, have been overlooked by Dr. Smith; one, for instance, by Mr. Liston, and another by Mr. Syme (both of which are included in Mr. Sands Cox's table), and a third in 1849, by Mr. Jones, of Jersey. But even allowing for these, the result is too favourable to be accounted for in any other way than by the non-publication of some of the unsuccessful cases. In sixty-two instances where the cause of the operation is stated with sufficient accuracy, Dr. Smith gives the following comparison between cases for severe injury and cases for chronic disease. In thirty of the former class, three out of five died, or 60 per cent. In thirty-two of the latter, the result, as might have been expected, was more favourable, the deaths and recoveries being equal, or a mortality of 50 per cent. The following further analysis of these cases, showing the mortality at different periods since the introduction of the operation, is also interesting. Previously to 1800, according to Dr. Smith, it had been performed fifteen times, the recoveries to the deaths being as two to three, or the mortality 66 $\frac{2}{3}$ per cent. These results had the effect of directing attention strongly to the operation, and during the twenty years subsequently to 1800, it became of much more frequent occurrence, although the ratio of mortality was very considerably increased. During this period there were performed twenty-four operations, of which eighteen proved fatal, giving a mortality of 75 per cent. During the next twenty years, ending with 1839, there are reported forty-two cases, of which twenty-nine were fatal, eleven successful, and two doubtful,—admitting the doubtful among the fatal,—and they give a mortality of nearly 74 per cent. During the last twelve years the number of operations reported is twenty-one, of which eighteen were successful and two fatal, being a mortality of a little over 14 per cent. In reviewing the history of this operation, thus briefly sketched, it will be seen that the per centage of mortality has not gradually diminished from the earliest introduction of the operation, but quite abruptly. It is difficult to account for this feature in the operation (says Dr. S.), except in a general way, for the ratio of accidents and injuries to chronic disease of the thigh remains nearly the same in both periods. We may suspect, however, that the cases were better selected, that the operation was more skilfully executed, and, above all, that much is due to the employment of anæsthetics. (*New York Journ. of Med.* vol. ix. 1852, p. 184.)

Since the publication of the last edition of this dictionary in 1838, there are records of nineteen

cases performed by British surgeons, of which the following is a brief outline.

In June, 1843, by Dr. Handyside, of Edinburgh, for malignant disease of the femur in a boy aged 13. The method employed was by anterior and posterior flaps. This case recovered favourably from the operation, but died 4 $\frac{1}{2}$ months afterwards of a malignant tumor in another part of the body. (*Lond. and Ed. Med. Journ.* April, 1845, p. 254.)

In Nov. 1844, by Mr. Sands Cox, of Birmingham. Successful. This case has been already referred to.

In Feb. 1846, by Mr. Whipple, of Plymouth, for diseased knee-joint, abscesses, and irregular growth from the femur, extending up to the trochanters. Anterior and posterior flaps. Successful. (*Lancet*, vol. ii. 1846, p. 883.)

In Sept. 1848, by Mr. Syme, for abscesses and necrosis following amputation of the thigh, which had been performed three months previously for a compound fracture. Anterior and posterior flaps. Twenty-one ligatures were applied. This was the first successful case in Scotland. (*Lond. and Ed. Month. Jour.* 1848, and *Med. Times*, Jan. 1849, p. 252.)

In Feb. 1849, by Mr. Jones, of Jersey, for sloughing and secondary hemorrhage after a lacerated wound of the thigh, sixteen days after the accident. Anterior and posterior flaps, the anterior being the longer. Fatal in twenty-seven hours. (*Med. Times*, March, 1849, p. 434.)

In Nov. 1849, by Mr. Wigstrom, 14th Light Dragoons, at Lahore, for diseased femur and profuse suppuration, extending nearly to the hips. Anterior and posterior flaps. Successful. (*Lancet*, vol. i. 1850, p. 411.)

The above, with the exception of Mr. Jones's case, are included in Dr. Smith's statistical tables.

In April, 1852, by Mr. Hancock, in the Westminster Hospital, for erysipelas and gangrene after compound fracture of the thigh. Operation seventeenth day after the injury; died almost immediately. (*Lancet*, vol. i. 1857, p. 31.)

In Jan. 1853, by Dr. R. J. Mackenzie, of Edinburgh, for extensive necrosis of the femur. Long anterior, short posterior flaps. Secondary hemorrhage and death on seventh day; went on well till that time. (*Ed. Med. and Surg. Journ.* 1854, p. 117.)

In Feb. 1853, by Dr. Fayrer, at Rangoon, for gunshot fracture. Died a month afterwards from tetanus, wound all but healed. (*Ed. Med. and Surg. Jour.* 1854, p. 418.)

In March, 1853, by Dr. Beatson, at Rangoon, for gunshot fracture. Secondary amputation. Anterior and posterior flaps. Died shortly afterwards. (*Ranking's Abstract*, vol. xxi. p. 182, and *Ind. Annals of Med. Science*.)

In April, 1853, by Mr. Charles Guthrie, in the Westminster Hospital, for malignant disease of femur. Anterior and posterior flaps. Fatal next day from hemorrhage. (*Lancet*, vol. i. 1853, p. 405.)

In May, 1853, by Mr. Wheatcroft, of Cannock, Staffordshire, for disease of hip-joint. Three flaps. Fatal in four hours. (*Lancet*, vol. i. 1853, p. 470.)

In March, 1854, by Mr. Adams, at the London Hospital, for malignant disease of the femur. Anterior and posterior flaps. Fatal in eleven days. (*Med. Times*, April, 1854, p. 349.)

In March, 1855, by Mr. Erichsen, at Uni-

versity Coll. Hospital, for compound fracture from railway injury. Anterior and posterior flaps. Died same evening. (*Lancet*, vol. i. 1855, p. 363.)

In July, 1855, by Mr. Tatum, in St. George's Hospital, for malignant disease of the femur. Large anterior and smaller posterior flap. Successful. (*Lancet*, vol. ii. 1855, p. 77.)

In March, 1856, by Mr. Curling, in the London Hospital, for malignant disease of the femur. Anterior and posterior flaps. Successful. Died ten months afterwards from chest disease, not malignant. (*Lancet*, vol. i. 1857, p. 6.)

In October, 1856, by Mr. Hancock, at the Charing Cross Hospital, for extensive necrosis of femur. Anterior and posterior flaps. Successful. (*Med. Times and Gaz.* Jan. 1857, p. 114.)

In March, 1857, by Mr. Stanley, in St. Bartholomew's Hospital, for malignant disease. Short anterior, long posterior flaps. Death in two hours. (*Lancet*, vol. i. 1857, p. 343.)

In Sept. 1857, by Mr. Lane, in St. Mary's Hospital, for compound fracture from railway injury. Short anterior, long posterior flap. Death same evening.

Thus we have had, since 1838, nineteen cases, with eight recoveries and eleven deaths. Thirteen of these were for various chronic diseases, and eight out of the thirteen recovered. The results of the operation, therefore, when undertaken for disease, have latterly been of a decidedly encouraging character. Unfortunately, however, the reverse has been as decidedly the case when it has been undertaken for injury. The remaining six cases were for this cause, and the whole of them were fatal. Three of these were primary, and three were secondary amputations. Equally unfortunate have been the results of the operation during the late war. Fourteen amputations at the hip-joint were performed by British surgeons in the Crimea, and the whole fourteen died. The French, however, according to Dr. Macleod, had one case of recovery at the hospital at Pera, in the winter of 1854. (*Ed. Med. Jour.* June, 1856, p. 1083.) Three more cases, all unsuccessful, occurred in the Punjab campaigns in 1848-9. (See *McRae, Ind. Annals of Med. Science*, April, 1857, p. 663.)

The mode of operation now generally practised is that with anterior and posterior flaps. It may sometimes be modified by making the anterior flap larger than the posterior, which, when practicable, is probably an improvement, because the flap falls by its own weight over the wound, and the discharge will escape with greater facility. The long anterior flap is recommended by M. Baudens. (*Bourgéry, Méd. Opér.* vol. i. p. 273.) M. A. Guérin suggests that the posterior flap may be made more even and regular by cutting from without inwards. For this purpose, after the disarticulation is completed, the knife should be carried under the limb to divide the integuments and remaining muscles from the surface upwards towards the wound. (*Méd. Opér.* t. i. p. 191.) Mr. Skey recommends two flaps to be formed from the integuments only, with a circular division of the muscles after the flaps have been reflected back. (*Op. Surg.* p. 357.) This latter plan has not yet, we believe, been carried out in practice. It is customary to employ about half a dozen interrupted sutures to maintain the edges of the flaps in apposition.]

No one can expect, however, this operation not to fail in a large proportion of the cases in which it

is attempted: this must always happen, let it be done in the most skilful manner possible. Yet, as there are unquestionably some descriptions of injury, where life must inevitably be lost if this proceeding be rejected, and experience proves that it sometimes answers, an important consideration is, what cases are most proper for it? Here I am decidedly of opinion, with Professor Thomson, that the examples in which it is particularly called for, and where no delay should be suffered, are those in which the head or neck of the thigh-bone has been fractured by a musket-ball, grape-shot, or small piece of shell. Eight or ten such cases, where amputation ought to have been done in the first instance, were brought in waggons several days after the assault on Bergen-op-Zoom into the hospital superintended by myself at Oudenbosch, and not one of these patients lived ten days after their removal. In the whole course of my professional life, I have never elsewhere witnessed so much suffering, or suppuration in such profusion. From each limb, at least three or four pints of matter were discharged daily. Had amputation at the hip been performed at first, some of these patients might possibly have been saved; at all events, I am certain that it was their only chance.

Larrey deems the operation proper, where the thigh has been shot off high up, or where the femur and soft parts near the hip have been broken, and extensively lacerated by a cannon-ball or pieces of shell. Here the operation (though perhaps the only chance) must almost always fail, because, as Professor Thomson observes, these injuries occasion a shock to the constitution, of which the patient mostly sinks either immediately, or in a few hours. (*Obs. made in the Mil. Hosp. in Belgium*, p. 274.) The truth of this observation I saw exemplified at Merxhem, near Antwerp, at the bombardment of the French fleet in that port; a shell burst between the thighs of one of the guards; tore and lacerated two-thirds of the thickness of the upper part of the right thigh; broke the ascending ramus of the ischium; lacerated the perineum and scrotum; and fractured the higher part of the femur. There was no hemorrhage of consequence; but the exposed lacerated surface of the soft parts was immense, and the unfortunate soldier, who lay with his hairs standing erect, and bereft of his intellectual faculties, sunk in the course of a quarter of an hour into a state of insensibility, and was quite dead in twenty minutes. However, there are numerous cases, in which the patients, after dreadful injuries of the upper part of the thigh, are less depressed and overcome, and live several weeks; facts clearly proving, that the operation ought to be attempted. Many instances of this kind are related by Mr. Guthrie. (*On Gunshot Wounds*, p. 134, &c.) [Mr. Guthrie thinks "It may be laid down as a principle, in all cases of accident, whether from shot, shell, or railway carriages, that no man should suffer amputation at the hip-joint when the thigh-bone is entire. It should never be done in cases of injury where the bone can be sawn immediately below the trochanter major, and sufficient flaps can be preserved to close the wound thus made. An injury warranting this operation should extend to the neck or head of the bone, and it may be possible even then to avoid it by removing the broken parts." (*Lancet*, vol. i. 1852, p. 555.)] Bad and incurable disease of the upper part of the femur (not the scrofulous hip, nor any other example in

which the pelvis is affected) may also require the performance of amputation at the hip-joint, as was recently illustrated in the practice of Mr. Syme, and in that of Sir Astley Cooper. The case in which Mr. Carmichael amputated at the hip was what is termed an osteo-sarcoma: the patient, a girl, nineteen years of age, died on the fifth day. (See *Trans. of the King's and Queen's College of Physicians, Ireland*, vol. ii. p. 357, &c.; and vol. iii. p. 158.) Dr. Mott's case was one of fracture of the upper part of the femur, ending in disease of the bone and extensive abscesses. The disease for which Delpech operated was necrosis of the thigh bone. The propriety of the operation in desperate cases is now perfectly established.

Thus, as M. Velpeau observes, a comminuted fracture, an osteo-sarcoma, a spina ventosa, any incurable disease of the femur extending above its shaft, gangrene, in short, any disease reaching to the vicinity of the hip, and so serious as to require the removal of the limb, are cases for amputation at this joint, provided the acetabulum and bones of the pelvis be unaffected. It is indispensable for gunshot wounds of the upper third of the thigh combined with fracture. (See *Nouv. Elém. de Méd. Opér.* t. i. p. 516.) It was performed by Mr. Mayo for a neuralgic affection of a thigh stump.

[Several of the more recent operations have been for malignant disease of the femur, and the question has arisen whether in all such cases it would not be better to amputate at the hip than in the continuity of the bone already diseased. That the disease does return rapidly in the stump when the amputation is performed in the continuity of the bone is unfortunately too well ascertained. Three cases of this kind occurring to Messrs. C. Guthrie, Lloyd, and Prescott Hewett, are recorded in the *Lancet* for 1850 and 1851, and in all these cases the surgeons are stated to have expressed their regret at not having amputated at the next joint above the disease. But, as it is observed in that journal, it is doubtful whether there is a sufficient guarantee against recurrence in taking off the limb at the hip-joint, to justify the immediate risk of life incurred by this hazardous operation. (See *Lancet*, vol. i. 1853, p. 406.)]

[STATISTICS OF AMPUTATIONS.]

[It is to be regretted that all our large public institutions do not furnish regular returns of the results of their principal operations. Such returns, showing not only the mortality, but the causes of death, and the period after the operation at which it takes place, would be of the greatest possible value in determining many questions relating to the subject of amputation.

In the absence of such sources of information, the following tables have been compiled from the principal statistical returns which have been published of late years. They produce, it will be seen, an aggregate of 5242 cases. Being derived from various sources, military and civil, from hospitals, both provincial and metropolitan, in this country, France, and America, and the cases having been subjected, therefore, to every variety of external influences, they may be supposed to afford a tolerably correct idea of the mortality after these operations.

The following are the authorities whose researches have been made available for this purpose.

B. Phillips.—640 cases of amputations of all kinds occurring in the previous four years in Great Britain, France, Germany, and America. (*London Med. Gaz.* 1838, vol. xxii. p. 457.)

Dr. J. A. Lawrie.—On the results of amputation. 276 cases in the Glasgow Infirmary from 1794 to 1838. (*London Med. Gaz.* Dec. 1840, vol. xxvii. p. 394.)

Steele.—Amputations in the Glasgow Infirmary from 1839 to 1848—284 cases. (*Ed. Med. and Surg. Journal*, 1849, vol. lxxii. p. 282.)

Statistical Reports of Operations in the London Hospitals, by the Medical Society of Observation, from 1837 to 1842—186 cases. (*MS. in Library of Med. Chir. Soc.*)

J. Erichsen.—140 amputations occurring in University College Hospital. (*Science and Art of Surgery*, p. 60.)

J. F. South.—54 amputations performed by him in St. Thomas's Hospital between 1835 and 1840. (*Translation of Chelius*, vol. ii. p. 905.)

Edw. Parker.—Statistical Account of Amputations in the Liverpool Northern Hospital, from March, 1834 to March, 1841—73 cases. (*London Med. Gaz.* vol. 28, 1841, p. 269.)

J. H. James.—On the Causes of Mortality after Amputation. 300 cases in the Devon and Exeter Hospital from 1816 to 1849. (*Transactions of the Provincial Med. and Surg. Association*, vol. xvii. 1850.)

Samuel Fenwick.—Operations in the Newcastle Infirmary from 1823 to 1843—225 cases. (*Ed. Monthly Journal of Med. Science*, 1848.)

E. L. Hussey.—Analysis of cases of Amputation of the Limbs in the Radcliffe Infirmary, Oxford—180 cases. (*Med. Chir. Trans.* vol. 31, p. 221, 1856.)

Dr. G. W. Norris.—Statistical Account of Amputations in the Pennsylvania Hospital, from 1830 to 1850—200 cases. (*American Journ. of Med. Science* for Aug. 1838, May, 1840, and July, 1854.)

Dr. Geo. Hayward.—Statistics of the Amputations at the Massachusetts General Hospital, from 1822 to 1850—146 cases. (*American Journ. of Med. Science* for May, 1840 and Jan. 1851.)

Henry Buel.—Amputations in the New York Hospital during nine years, from 1839 to 1848—91 cases. (*Amer. Journ. of Med. Science*, vol. xvi. 1848, p. 33.)

Dr. Stephen Smith.—Statistics of Amputation at the shoulder-joint—39 cases. (*New York Journ. of Med.* Jan. 1853); and of Amputation at the hip-joint—98 cases. (Same Journal, Sept. 1852.)

Dr. Markoe.—On Amputation at the knee-joint—46 cases. (*New York Journ. of Med.* Jan. 1856, p. 45.)

Malgaigne.—Amputations in the Parisian Hospitals during ten years, from 1836 to 1846—519 cases. (*Erichsen's Surgery*, p. 60, and *London Med. Gaz.* Sept. 15, 1848.)

Guthrie.—(*Commentaries on the Surgery of the War from 1808 to 1815*. Ed. 5, 1853, pp. 150–154.)

R. Alcock.—(*Medical History of the Spanish Legion*. London, 1838.) 123 cases.

Crimea.—500 cases, occurring in the latter half of the late war, furnished to the writer by the kindness of Mr. G. E. Blenkins, Grenadier Guards.

*Statistical Table, showing the Mortality after
Amputations of all kinds
(exclusive of fingers and toes.)*

	Number of Cases.	Fatal.	Mortality per Cent.
Phillips . . .	640 . .	150 . .	23.43
Lawrie . . .	276 . .	100 . .	36.3

Amputations at the Knee-Joint.

The cases collected by Drs. Stephen Smith and Markoe are forty-six in number. To these may now be added seven cases occurring in the Crimea, and seven others by Messrs. Syme (2), Potter, Jones, Markoe, Lane, and Hussey. Only two of these latter, and three out of the seven Crimean cases were true disarticulations of the knee; in the remainder the articular end of the femur was removed.

	Number of Cases.	Fatal.	Mortality per Cent.
Markoe . . .	46 . .	17 . .	37
Crimea . . .	7 . .	4 . .	57.14
Other cases . .	7 . .	0 . .	0
Total . . .	60 . .	21 . .	35

Mr. Fergusson's cases are not included, their number not having been stated.

Amputations at the Hip-Joint.

If, to the cases given in Dr. Stephen Smith's tables in the *New York Journal of Medicine*, 1852, (see *ante*, p. 118) be added those which have been since recorded, and which have been alluded to in this article, the total number will be found to amount to 139, with the following result:—

Number of Cases.	Fatal.	Mortality per Cent.
139 . . .	91 . .	65.46

The cause of operation is not ascertainable in all these cases, but in 102, where it has been recorded, we find 62 were for injury and 40 for disease:—

	Number of Cases.	Fatal.	Mortality per Cent.
Injury . . .	62 . .	47 . .	75.8
Disease . . .	40 . .	21 . .	52.5

On examining these statistics, the first striking fact is, that although the per centage varies greatly in different hospitals and in different localities, the mortality after all amputations, calculated from a total of more than 5000 cases, is as high as 33·25 per cent., or one in every three of the patients submitted to the operation. So fatal a result was scarcely suspected, till Mr. Benjamin Phillips drew the attention of the profession to the subject in 1838.

The next fact clearly established, is the greater mortality after amputations performed for injury than after those performed for disease. This, also, would not at first sight appear probable; the operations for injury being for the most part done on robust, healthy individuals, and those for disease on persons debilitated by long continued pain and suppuration. The difference appears to depend in a great measure on the shock which the injury has inflicted on the system, since the deaths which take place during the first three days after the operation are much more numerous in the amputations for injury than in those for disease. But in addition to this cause, it has been found that the mortality from secondary morbid processes, such as inflammation of internal organs, erysipelas, phlebitis, pyæmia, &c., is also greater in the one class than in the other. The occurrence of phlebitis was found, by Mr. James, in the Devon and Exeter Hospital, to be confined almost entirely to the primary amputations for injury. The occurrence of erysipelatous inflammations and of pyæmia will, no doubt, always vary greatly in different institutions; it will be less frequent in hospitals situated in the agricultural districts than in the more crowded institutions and vitiated atmosphere of a manufacturing town. Mr. James thinks that the nature of the injury will have a material influence on the result, and that those cases will be most fatal which involve the greatest degree of crush or laceration, and this more especially in the lower extremities, partly from the larger mass disorganised, partly from the greater inability of the system to repair the injury, the impression produced by which does not pass away even when the injured part is completely removed. (See *Trans. of Prov. Med. Ass.* vol. xvii. 1850, p. 81.) The same author has pointed out that the mortality varies also in the operations for disease, being least in the chronic diseases of bones and joints, greatest in cases of old ulcers, in acute gangrene, and acute suppurative inflammations. (Op. cit. vol. xviii. 1851, p. 332.) Exhaustion and hectic, and the supervention of tubercular disease at a later period are, perhaps, the most frequent causes of death after amputations for disease; but these have but little share in the mortality after amputations for injury.

The next point is the comparison between the primary and secondary operations for injury. In the table which has been given, the advantage will be seen to be in favour of the former, to the amount of 16 per cent.—the mortality being 30 per cent. in primary and 46 per cent. in secondary operations. This disproportion is, doubtless, partly owing to the circumstance that the intermediary or compulsory operations are in most instances recorded with the secondary, and the apparent mortality of these latter is thereby very considerably increased. If this source of fallacy were removed, there is reason to believe that in civil practice

operations performed when the *true* secondary period has arrived (that is, when the inflammatory symptoms have subsided, and the suppurative stage is fully established,) are but little, if at all, more fatal than primary. Secondary amputations are seldom fatal from shock, and they are therefore found to be most successful, as compared with primary, in the larger portions of the limbs, where the effects of the shock are found to operate most prejudicially in primary operations. In amputations of the thigh, it will be seen that the proportion of mortality is reversed, and is considerably in favour of secondary instead of primary operation. This remark applies to the military as well as to the civil cases.

The success of secondary amputation, however, should not be considered as an argument in favour of delayed operation; since, as has been before explained, many will die before the favourable period arrives, and many others will undergo amputation as a matter of necessity in the intermediary period, and under the most unfavourable circumstances. The table, therefore, although it may exaggerate the mortality after secondary amputations properly so called, most probably does not at all exaggerate the *advantage* to be gained from immediate operation in all cases where there is no hope for the ultimate preservation of the limb.

Primary amputations, it will be observed, have been more successful in military than in civil practice: while on the other hand, civil surgeons have succeeded somewhat better than military with their secondary operations. Some reasons for the greater success of primary amputation in military surgery have already been given (*antè* p. 49); but another has been suggested by Mr. James, in the fact that a large number of the military operations are performed for “compound fractures from musketry, in which the injury is by no means equal in extent, and consequently in degree of shock to that which occurs in those accidents which in civil practice are more generally submitted to amputation.” On the other hand, the resources at the command of the military surgeon are often insufficient for the satisfactory treatment of compound fractures, and therefore when the secondary period arrives, the patients are in a less favourable condition for operation than those which have been treated in a civil hospital.

The mortality increases in a nearly direct ratio with the bulk of the part removed—rising from 10 per cent. in the fore-arm to 41 per cent. in the thigh, and 65 per cent. at the hip-joint. It is to be regretted that sufficient data do not exist for estimating the mortality in the upper as compared with the lower third of the thigh, and of the upper with the lower third of the leg. Another circumstance deserving of attention is, that the disproportion in the mortality of amputations for injury and those for disease is greater according to the size of the part removed. The advantage on the side of disease is as much as 30 per cent. in the thigh; but is not more than 2 per cent. in the arm; while in the fore-arm the proportion is reversed, and the advantage is slightly on the side of amputations for injury. By making a similar comparison of primary with secondary operations at different levels, it will be seen that the advantage is greatly on the side of primary amputation, in the case of the fore-arm and arm, that this difference becomes less striking in the leg, and

that the proportion is reversed in the thigh, in which situation secondary amputation has the advantage. In this respect secondary amputation has some analogy with amputation for disease, *i. e.* it is more successful, as compared with primary, in proportion to the size of the part removed.

Space will not permit of a more lengthened comment on the figures which have been given; it is hoped, however, that they may prove not altogether useless to those who may be prosecuting further inquiries into the subject.] *James R. Lane.*

ANASTOMOSIS (from *ἀνά* through, and *στόμα*, a mouth). Anatomists and surgeons imply by this term the communications of the blood-vessels with each other, or their running and opening into each other, by which the continuation of a free circulation of the blood is greatly ensured, and the danger of mortification lessened. In cases of aneurism, when the main artery of a limb is tied, the anastomoses of the branches given off above the ligature, with other branches below it, form at once a channel through which the lower part of the limb is supplied with blood. Were there no such arrangement in the human body as anastomoses, aneurisms could never be cured by a surgical operation. So infinitely numerous, indeed, are these anastomoses, that they do the office of the subclavian, carotid, and external and internal iliac arteries, when these vessels are tied, and upon this fact is founded the success of some of the most brilliant operations in modern surgery. Nay, such has been the providence of nature in this respect, that even when the thoracic aorta has been completely obstructed, the channels for the conveyance of the blood to the lower extremities have yet been found adequate to that purpose. This was proved in an example where the obstruction had been gradually produced by disease, and the anastomosing vessels of course had had time for enlargement; for this is a very different case from that in which a ligature is suddenly applied to the aorta; though, as far as can be deduced from the particulars of some experiments made on dogs by *Sir Astley Cooper*, and in one operation in which he tied the human abdominal aorta (*Surgical Essays*, part i. p. 101), blood will still pass to the lower extremities in sufficient quantity

for their nutrition. At least this inference is safely deducible from the very memorable operation to which I have referred, subject to one important condition, viz. that there be no additional cause of impediment to the passage of blood to the lower extremities, beside the ligature above the bifurcation of the aorta. When Sir A. Cooper tied the human aorta in the abdomen, the experiment was made as the only possible means of hindering a man from bleeding to death, who had a large aneurism of the external iliac artery actually beginning to bleed, and extending too high to admit of anything else being done. Now, although the unfortunate patient was not saved, and it must be acknowledged that the chances of any other result were very small, the case furnished the important proof, that if the abdominal aorta be suddenly and completely obstructed, the blood may yet pass in adequate quantity to the lower extremities, provided there exist no other cause of impediment to the passage of the blood into those members; for on the side occupied by the aneurism the circulation in the limb was stopped, while in the opposite limb the circulation and natural warmth were preserved. To this subject I shall hereafter return. (See AORTA.)

The changes which take place in the arterial system of the limb, when the main artery is rendered impervious by the application of a ligature, are well described by Mr. Hodgson: "The blood meeting with an obstacle to its progress through the accustomed channel, is thrown in greater quantity and with greater force into those branches which arise above the seat of the obstruction. The ramifications of these branches, in consequence of the unusual influx of blood, undergo a remarkable dilatation; the more minute vessels also, by which they anastomose with corresponding ramifications, arising from branches given off below the obstruction, are from the same cause sufficiently enlarged to allow a free passage of the blood into the inferior trunks of the limb. At first the circulation is in this manner carried on through a congeries of minute anastomosing arteries: in a short time a few of these channels become more enlarged than the rest: as these increase in size, the smaller vessels gradually collapse, and ultimately a few large communications constitute permanent channels through which the blood is transmitted to the parts that it is destined to supply. This is one mode by which a collateral circulation is established."

"But in some situations more direct and ostensible inosculation are provided; so that when one channel is obstructed, the blood passes through the other in a sufficient stream for the nourishment of the part which it is destined to supply. Under these circumstances no dilatation of the collateral branches is necessary: the circulation in such instances may be said to be constantly carried on through inosculating trunks. These great communications principally exist in the extremities of the body where the dilating impulse which the blood receives from the heart is of course diminished. Thus the radial artery inosculates freely with the ulnar; the anterior with the posterior tibial; and the internal carotid with the vertebral arteries. Two modes, therefore, exist, by which arteries communicate with each other—the anastomoses of minute ramifications and the direct inosculation of trunks." (See Hodgson, *On Dis. of Arteries and Veins*, p. 234.)

[It may be as well to remark that when the circulation is carried on by anastomosing branches after the obliteration of the main artery of a part, the current of the blood will be reversed in the branches which are connected to the main artery on the distal side of the obliteration, and which are to convey blood into it. After the lapse of some months the anastomosing vessels which have taken upon themselves the office of the principal artery, not only become enlarged, but assume a tortuous disposition, and a pulsation may be detected in them long before any can be felt in the principal arteries on their distal side. Indeed, the pulsation of the main arteries may remain scarcely perceptible for years after the application of a ligature.

Although it appears to be fully established that the circulation of the blood may be effectually carried on by the anastomosing branches after a ligature has been applied to a main artery in any part of its course, yet it may be well for the scientific surgeon to bear in mind that great differences exist as to the number and size of these anastomosing vessels in different parts of the body. To such an extent is this the case, that a ligature applied to a main artery in some positions will be ineffectual in arresting hemorrhage, or perhaps even in curing an aneurism, while in other positions the anastomosing branches may be so few and small as to be scarcely adequate under particular local or constitutional circumstances to maintain the vitality of the limb. My attention was forcibly drawn to this subject many years ago, when house surgeon at the Lock Hospital. Having been fortunate enough to procure for dissection the body of a person who had died in that institution without friends, I was desirous of obtaining a minute injection of the blood-vessels of the left side of the head and neck, and of the left upper extremity. With this object in view, an injecting pipe was placed in the aorta, close to the heart; firm ligatures were applied to the descending thoracic aorta and to the arteria innominata. It was expected by these arrangements that the injection would be prevented passing into the right arm and right side of the head and neck. The next day, however, on removing the right arm from the body, it was found that its blood vessels, as well as those of the right side of the head and neck, were minutely injected. It was concluded that the ligature on the arteria innominata must have given way. On examining the vessel and the ligature, however, all was perfectly secure. It was now at once seen that the injection contained in the right arm and right side of the head and neck must have passed through the circle of Willis, and thus have been conveyed, contrary to the usual course of the circulation, by the right carotid into the innominate artery, and by the right vertebral into the subclavian. I have ever since had my doubts whether a ligature applied to the arteria innominata alone would be found to interrupt the circulation sufficiently either to cure an aneurism, or to arrest hemorrhage in the subclavian or carotid arteries of the right side. At any rate, I should expect the circulation to be too free to admit of a coagulum forming on the distal side of the ligature, an occurrence so necessary to prevent secondary hemorrhage on the separation of the ligature. On this account, should I ever be called upon to tie the innominate artery

for aneurism of the subclavian artery, I have long made up my mind that it would be sound practice to ligature conjointly with the innominate artery the common carotid close to its origin. With respect to the aorta itself, if this vessel should be again ligatured in the human subject, it is evident that the supply of blood to the lower extremities would be greatly influenced by the level at which the ligature was applied to that vessel. If below the inferior mesenteric artery, the position selected by Sir Astley Cooper, the small anastomosing branches of the lumbar arteries, with the ilio-lumbar, lateral and middle sacral arteries, aided by the communications of the epigastric with the mamma interna, would be the principal channels depended upon, which it is to be feared will never be found sufficient to carry on the circulation in the lower extremities, whereas, if the ligature be applied above the inferior mesenteric artery the free anastomosis this vessel has with the superior mesenteric artery would ensure an ample current of blood into the aorta itself for the support of the lower limbs. The instances here given may be sufficient to draw the attention of surgeons to the important fact that it is by no means a matter of indifference at what level on a main artery a ligature should be applied, when it is considered that the double object of curing an aneurism and of carrying on the circulation of the blood is to be provided for.]

The best general account of the anastomoses in relation to aneurism is contained in *Scarpa's Treatise on Aneurism*, more especially the Italian edition, which is embellished with beautiful engravings.

ANÆMIA (from α priv. and $\alpha\iota\mu\alpha$ blood. Deficiency of blood). This term implies such a diminution of the quantity of blood in the sanguiferous system, or in any part of it, as is inconsistent with health. By medical writers it is sometimes restricted to a state of bloodlessness from defective hæmatisation, but the condition of the system is strictly analogous, whether produced directly by accident, by the abstraction of blood as a remedy, or by disease. In all cases the constitution of the blood remaining in the system is altered; the proportions of its constituents being changed by the absorption or imbibition of albuminous and saline fluids from the alimentary canal or the tissues through which the vessels permeate. The most important change is a diminution in density, produced by a smaller proportion of solids and especially of red corpuscles, the proportions of fibrine, albumen, fatty matters, and salts remaining little or not at all affected. After repeated hemorrhage, furnishing the least complicated form of anæmia, the red corpuscles have been known to sink to 27 in 1000 parts, and they are said to become relatively richer in hæmatin and poorer in globuline; their specific gravity being greater, and their tendency to sink in the liquor sanguinis increased (Lehmann). Thus true anæmia implies a degree of hydræmia, but the latter must not be mistaken for its essential character.

Although the effects of a diminution of the quantity of blood in the blood-vessels are in many respects similar, from whatever cause it may be produced, yet they differ somewhat according as the diminution may have arisen from antihygienic influences or direct loss; and in the latter case according to the rapidity of the flow, the quantity

extravasated, and the previous state of the individual. Anæmia often arises from, and is accordingly complicated with, disease of one or more of the organs of hæmatisation, as of the lungs or liver; but the study of the morbid effects of direct loss of blood is essential to a just appreciation of its symptoms and results. The immediate effects of a sudden loss of a considerable quantity of blood, the quantity varying according to the previous state of the sanguiferous system and the general constitution of the individual, are at first a feeble and slow, and then a quick and fluttering pulse, sense of sinking, slowness of respiration interrupted with deep sighs and eructations, pallor of the countenance and especially of the lips, pallor and coldness of the general surface, vertigo, loss of consciousness, and syncope. When the bleeding has been arrested, not having proved sufficient to cause death, consciousness gradually returns and is usually attended with nausea, vomiting, irregular sighing and yawning, the return of the pulse, of the colour, of the warmth of the body, and recovery. When the flow continues a fatal result may be rapidly produced, the syncope may return again and again, the respiration becoming diaphragmatic and nearly imperceptible, and the patient may expire in one of the fainting fits, particularly if in an erect posture. Or there may be gradual sinking, with the faculties entire to the last; or delirium may occur with or without convulsions, followed, especially in children, by coma; or there may be stertorous breathing and involuntary discharge of the contents of the bladder and lower bowels. With these symptoms there is first an intermittent, then an imperceptible pulse, restlessness and jactitation, tremors and shudderings, struggles for breath, tetanic spasms or convulsions, loss of animal heat, and death.

When a large and rapid loss of blood does not result in death, reaction usually supervenes. The pulse becomes quick and more or less sharp and bounding although easily compressed; there are palpitations and throbbings in different parts of the body, particularly in the arteries of the head, and often in the aorta; the trunk is often hot while the extremities are cold; there is hurried respiration, often attended with anxiety and sighing, and an excessive desire for fresh air; pain or sense of pressure in the head with intolerance of light and noise; agitated sleep with dreams, and, on awaking, delirium, or a sense of impending dissolution. There is also intense thirst. During this state convulsions and coma are very liable to occur, particularly in children, and fatal exhaustion may suddenly supervene, especially on assuming an erect posture, or on any considerable exertion. When the reaction terminates in recovery it is succeeded by a state of debility with more or less of the general symptoms of anæmia presently to be described.

When bloodlessness is produced by losses in small quantities, frequently repeated, the effects are somewhat different. They are slow and insidious in proportion to the frequency of the repetition and the smallness of the quantity. They are extremely various; partaking, on the one hand, of those which have been described as resulting from excessive loss and the consequent reaction; and, on the other, of the symptoms of permanent anæmia however produced; and thus depend upon, or are very materially modified by, the age, temperament, and constitution of the individual.

This leads to the consideration of anæmia as a *chronic disease* produced by less direct causes, operating more slowly, and gradually diminishing the mass of blood in the body. The more important of these causes are, prolonged abstinence; an habitual deficiency of the staminal principles of nutrition; the absence of some element of the blood essential to cell-growth and hæmatisation; continued debility of the functions of primary digestion; diseases of any of the organs or tissues by which the supply of materials, or the combination of the elements, or the production of the proximate principles and vital cells of the blood are effected; or of the channels of conveyance; and particularly diseases of the lungs, the liver, the pancreas and mesenteric glands; continued subjection to various antihygienic influences, as a vitiated or insufficiently renewed atmosphere, want of exercise, deprivation of the solar rays, the depressing passions, or any cause of depression of the nervous energies of sufficient duration to interfere with the processes of hæmatisation; diseases attended with profuse discharges, acting as a drain to the constitution, as large abscesses or diabetes; sexual excesses, and the like. Anæmia is often employed as a relative term, and we have no precise standard of the quantity of blood in the body, individuals of different constitutions have more or less in health, and some are habitually anæmic; so that, whether produced by voluntary or accidental direct loss, or by antihygienic causes, it is only by its effects that it becomes a disease. Well marked instances of chronic anæmia are however observable after large depletions employed in the treatment of acute diseases, the loss of blood from accidents, and the draining of blood from repeated hæmorrhages; it is often found to prevail in large proportions of a population, in individuals subject to starvation and famine, and in masses of people residing in close dark localities, as in coal and other mines, and well marked instances are observable among various classes of operatives in our manufacturing towns. Chronic anæmia is occasionally produced mechanically by obstruction of the œsophagus or of the thoracic duct.

The symptoms of chronic anæmia, whether the insidious effect of small but frequently repeated losses of blood, visceral disease, or antihygienic influences, are in most respects the reverse of those which result from plethora. The blood, owing to the deficiency of red corpuscles, is deficient in its usual bright red colour, and the animal tissues generally reflect a much paler colour than natural. The capillaries are small or scarcely perceptible, and the cutaneous veins pale and collapsed. When a ligature is applied to the trunks in the limbs the veins become slowly distended; they are also readily emptied by friction and slowly refilled. The countenance and integuments generally are blanched and waxy, the conjunctiva is pale and its capillary vessels disappear altogether, the mucous membranes are pale, particularly in the prolabia, the gums, the mouth and fauces, and the tongue. The action of the heart is feeble, the pulse weak, small, in extreme cases scarcely to be felt, readily quickened by mental or physical excitants, and often fluttering or palpitating with a sharp impulse, quite distinct from the steady strong impulse of hypertrophy. There is a sense of sinking, and even syncope may occur followed by palpitation, on quickly assuming the erect posture.

Hæmatic murmurs are produced in various parts of the vascular system; they may be heard with the stethoscope, or even with the naked ear, especially over the base of the heart and the large vessels at the root of the neck, but their diagnostic value must not be too highly estimated, as they are observable in impoverished states of the blood where no degree of emptiness exists, and in many cases are produced solely by external pressure on the parietes of the weak and easily compressible vessels, diminishing the calibre of the tubes. The respiration is short, feeble, and easily hurried. The animal heat is ill sustained, and the surface and extremities are below the natural temperature. There is great nervous sensibility with intolerance of light and sound, scintillations, and other amaurotic symptoms, tinnitus aurium, muscular debility, slight efforts producing fatigue, with languor, tremors, and want of capacity for sustained exertion. There is great debility of the functions of the stomach with deficiency of gastric juice, loss of appetite, occasional nausea, cardialgia, costiveness or irregularity of bowels, flatulent distension, and other symptoms of dyspepsia. The urine and secretions generally are pale and watery, and in females the menstrual fluid is pale and scanty. To these symptoms are often added others which depend on reaction, such as palpitations and throbbings, and extremely severe headaches: and in extreme cases most of the effects of direct loss of blood supervene, extremely hurried and oppressed breathing, gasping, tremors, spasms, convulsions, and coma. When of long continuance, general atrophy is the usual concomitant of anæmia, the blood also becomes in a remarkable degree hydræmic, giving rise to another train of effects, such as œdema, dropsical effusions, and softening of the tissues and internal organs, as of the brain, or to diarrhœa and profuse perspirations; the diminished tone of the vital solids and of the exhalant orifices, and the poverty of the blood explaining many of these effects. Anæmia predisposes to hysteria, epilepsy, chorea, and other nervous affections, and may arrive in various ways at a fatal termination. The patient is often carried off in a fit of syncope, or convulsions, or coma, or may sink more gradually, exhausted, with effusions in the lungs, pericardium, brain, or abdomen. When death occurs, the heart itself the arteries and veins are almost empty, containing only a sanguineous serum; the tissues and organs are all pallid; little or no blood flows from the parts divided, and the viscera generally are comparatively bloodless.

Thus anæmia not only occurs after accidents and operations attended with loss of blood, but may precede them. It is found during convalescence after acute affections, particularly where active depletion has been resorted to; it may complicate any surgical disease, and the statements in this article show the importance of attending to the condition of the system as respects the quantity of blood contained in the vessels, especially in relation to blood-letting and depleting measures generally. Both inflammation and hemorrhage occurring in a state of general anæmia have an unfavourable tendency, owing not only to the deficiency of blood but also to the defective reactionary process and the low degree of vitality in the plastic materials derived from the blood. The blood of anæmic subjects cannot be spared. More-

over, anæmia is generally complicated with other morbid states of the blood, the continued emptiness of the vessels being favourable to the absorption of unassimilable materials and the defective nutrition of the organs unfavourable to secretion and depuration; hence blood, in its constitution essentially anæmic, becomes diluted with water, and the blood-vessels may be as full or even fuller than natural, producing a distinct train of symptoms. (*Vide Hydræmia; Spurious Anæmia.*) Anæmic blood is also extremely liable to be poisoned by foreign matters introduced from without, or by retained secretions and excretions.

Local Anæmia.—Deficiency of the supply of blood to a part may be produced by various causes diminishing the calibre or obliterating the artery by which the supply should be maintained. Tumors of various kinds, the spontaneous coagulation of the blood in an artery, disease of the coats of an artery leading to the deposition of fibrine, the obstruction of an artery by fibrinous flakes transported from a distance, as from the valves of the heart, are so many mechanical causes. It may also be produced by an excessive determination of the current of blood to other parts. This local anæmia may be totally independent of the quantity of blood in the system, or its quality. The quality of the blood in the anæmic part is not so much changed and especially the proportion of corpuscles is but little diminished. The effects on the part are, however, very similar to those produced by general anæmia, except that they are often carried much further. This partial anæmia, however produced, may disturb or completely arrest the function of the part, producing loss of motion and sensation, coldness, and ultimately atrophy and disorganisation. Obstruction of the coronary arteries produces debility and atrophy of the heart itself. Disease of the cerebral arteries, or ligature of their trunks, or obstruction by fibrinous clots (*Dr. Kirkes, Med.-Chir. Transac. vol. xxxv. p. 281*), occasioning an interruption to the flow of blood, produce disturbance of the cerebral functions, softening of the brain, and even gangrene, with convulsions, spasms, paralysis, and all the usual symptoms and sequelæ of such disturbance. Arrest of the flow of blood to a secreting organ produces analogous results, with a diminution of the proper secretion and the ultimate poisoning of the blood with the effete matter that ought to have been eliminated. The complete obliteration of the main artery of a limb, if the blood is not supplied in time by the collateral circulation, results in gangrene. The effects of local anæmia differ greatly according to its degree, and as the arrest may have been sudden or slow and insidious. Analogous, although not quite identical effects, result from the spurious anæmia of a part, the blood being defective in some of the principles essential to nutrition, although the absolute quantity supplied may not have been diminished.

Treatment.—When blood is suddenly extravasated in large quantity, so as to compromise life rapidly, the first duty of the surgeon is to place the patient in the best position for the maintenance of the arterial circulation and the respiration, taking care that the bleeding vessel or organ is so directed that the flow of blood may be opposed by gravity. If the bleeding continues, we then proceed to arrest it by such surgical measures as the

nature of the case may dictate. If the flow has been so great as to produce enduring syncope or apparent death, transfusion is the remedy. When blood is lost slowly or in repeated small quantities, various surgical appliances and internal remedies are resorted to. (*Vide Arteries, ligature of—compression of—cauterisation of—hemorrhage—transfusion.*)

When true anæmia, less urgently compromising life, complicates surgical diseases, the treatment must depend on the particular disease, but the anæmic condition must never be lost sight of. The remedies are hygienic and medicinal. The first, consisting in the strictest attention to a good system of diet, and the free respiration of a pure air, with a judicious employment of exercise where not forbidden by local disease, and due regard to sleeping and watching, cheerfulness of mind, and the avoidance of excesses of all kinds. As in all instances of direct debility the greatest care should be taken that the vital power is not taxed excessively and thereby exhausted, either in demands made on particular functions of life, or upon the general nervous and muscular systems. Hence the quantity and the quality of the food must be adjusted to the digestive powers of the individual and the special demands of the system. For the recovery of the nutrition of the adipose tissues the food must contain a due quantity of the oily element, and in like manner a sufficient proportion of the albuminous or protein principles is necessary to form a perfect pabulum for the nutrition of the muscular and vascular systems. The medical treatment consists in tonics, chalybeates, restoratives, and stimulants. The selection of medicines of these classes must depend on the particular case, and be left to the judgment of the practitioner. In some instances the anæmia appears to depend on the deficiency of a particular element in the blood, as of iron, the administration of which constitutes the first and most essential part of the treatment. Care is necessary in the use of this medicine. If given in too large a quantity, absolutely or relatively, as respects the other constituents of the blood or the elements of the food, or if given unnecessarily, it may act as a foreign material received into the blood, and if unassimilated by the vital fluid may produce congestion or irritation in the brain, lungs, and other organs, with their ordinary symptoms, as headache, pleuritic pains, or hurried respiration. Where anæmic blood appears from the state of the adipose tissues to have failed in their nutrition especially, cod liver oil is useful and may frequently be given advantageously at the same time as iron. Where the primary digestion is at fault, bitters, and chalybeates, and in depression of the nervous powers, valerian, assafoetida, musk, and repeated judiciously regulated doses of opium, and other remedies of that class, may be useful. Where anæmia has been produced suddenly by loss of blood, diffusible stimulants, of which wine, ether, and opium, are among the best, are often absolutely necessary, and in the more chronic cases these are useful, and may even be essential adjuvants. H. Ansell.

ANÆSTHESIA IN SURGICAL OPERATIONS. [The term anæsthesia, from α , privative, and $\alphaἰσθάνομαι$, "I feel," has long been used by medical authors to denote the loss of common sen-

sation in any part of the body, as a pathological condition, and it has of late been very generally applied to express the effects of medicines which are inhaled to prevent the pain of surgical operations. These medicines belong to the class of narcotics, or more properly narcotico-irritants; they suspend the action of the other senses as well as that of touch or feeling, and also induce a temporary loss of consciousness. The term narcotism, therefore, is more in accordance with the usual language of physiology as a definition of their effects; still anæsthesia expresses the purpose for which the medicines are inhaled, and it seems likely to remain in use, and the agents themselves will probably retain the name of anæsthetics.

Attempts to prevent the pain of surgical operations are not peculiar to our own age, and, according to Pliny and Dioscorides, who say that wine of the root of mandragora was used for this purpose, the attempts were not unsuccessful. A Chinese surgeon, named Hoa-tho, who flourished between 220 and 230 of our era, is also represented to have made patients insensible to operations by a preparation of hemp. The present practice of inhalation for the prevention of pain was, however, not suggested by the usage of the ancients, but originated from an observation of Sir Humphry Davy respecting nitrous oxide gas. He found that this gas relieved the pain he was suffering whilst cutting a wisdom tooth, and he actually suggested that it might be used to prevent the pain of surgical operations. This suggestion was published by Sir Humphry Davy at the end of the last century, but was not acted on till 1844, when Mr. Horace Wells, a dentist of Connecticut, used it with more or less success in a few cases of tooth drawing, and even larger operations. He, however, gave up the practice in disappointment, on account of the gas sometimes failing to take the desired effect. In less than two years after this, a dentist of Boston, Massachusetts, named Dr. W. T. G. Morton, who had seen some of the attempts of Mr. Wells, tried an agent which had often been used in the lecture-room as a substitute for nitrous oxide, to produce the ordinary exhilarating effects of that gas. This agent was sulphuric ether, and with this Dr. Morton was completely successful. It is to him, in fact, that the world is indebted for the actual introduction of the present practice of preventing the pain of surgical operations. Sulphuric ether was first exhibited as an anæsthetic in September, 1846; it soon came into general use in all parts of the civilised world, and was effectual in preventing the pain of surgical operations, in all cases in which it was properly administered. In November, 1847, the use of sulphuric ether was suddenly, and almost entirely, superseded by that of chloroform, which was introduced by Dr. Simpson, of Edinburgh, who was induced to try it from the knowledge that it formed the active ingredient of a liquid called chloric ether, which had occasionally been exhibited in the form of vapour, with more or less success, by Mr. Jacob Bell and others in London.

Chloroform or terchloride of formyle, consists of two atoms of carbon, one atom hydrogen, and three atoms chlorine. It is prepared by distilling rectified spirits of wine with chlorinated lime and water. It is a clear, colourless liquid, having a hot and intensely sweet taste. Its odour is nei-

ther strong nor unpleasant. It is a heavy liquid, having a specific gravity of 1.503 at 60° Fah. Notwithstanding its weight, it is a very mobile liquid, and when dropped from the lip of a small phial, the drops are extremely small, nine drops, being equal to only two minims. It is soluble in alcohol and ether in all proportions, but it requires nearly 300 parts of water for its solution. When dropped into water, it falls to the bottom of the vessel, and acquires an oily appearance. Chloroform is very volatile, boiling at 140° Fah. The specific gravity of its vapour is 4.2. Under ordinary circumstances, the vapour of chloroform has no separate existence, but is always mixed with air. It can exist in a pure state only when the temperature is raised to 140° or upwards; or when the pressure of the atmosphere is in a great measure removed by the air-pump.

The following table shows the amount of vapour of chloroform in 100 cubic inches of the mixture of air and vapour, when the air is saturated at the different temperatures indicated.

Temp. Fah.°	Air.	Vapour.
40 . . .	94 . . .	6
45 . . .	93 . . .	7
50 . . .	92 . . .	8
55 . . .	90 . . .	10
60 . . .	88 . . .	12
65 . . .	85 . . .	15
70 . . .	81 . . .	19
75 . . .	78 . . .	22
80 . . .	74 . . .	26
85 . . .	70 . . .	30
90 . . .	65 . . .	35

As the effects of chloroform, when inhaled, depend entirely on the quantity of vapour present in the air which the patient breathes, the effect of temperature on its volatility is of great practical importance. The air does not indeed become fully saturated with vapour during the process of inhalation, but the effects of temperature are relatively as great as if it did.

In order to facilitate the description of the effects of chloroform, the writer of this article has been in the habit of dividing them into degrees. The term degree is used in preference to stage, as during the action of chloroform, the slighter degrees of narcotism occur in the later stages of its influence, during the recovery of the patient, as well as in the beginning. The division into degrees is made according to symptoms which seem to depend entirely on the state of the nervous centres, and not according to the amount of anæsthesia, which, there is good reason to conclude, depends, in a great measure, on the local action of the chloroform on the nerves. The different degrees of narcotism glide insensibly into each other.

In the first degree are included all the effects of chloroform that exist while the patient retains a perfect consciousness of where he is and what is occurring around him. This degree constitutes all that a person recollects of the effects of the vapour, except when he happens to dream and remembers it afterwards. In the second degree of narcotism, there is no longer correct consciousness. The mental functions are impaired, but not necessarily suspended. The patient usually appears as if asleep in this degree; but if his eyelid be raised he will move his eyes in a voluntary manner. There are occasionally voluntary movements of the

limbs ; and although the patient is generally silent, he may nevertheless laugh, talk, or sing. In the third degree there is no longer any voluntary motion. The eyes are not directed towards any object ; and although the limbs may move, they are not directed to any purpose. The pupil of the eye is generally inclined upwards, and is usually somewhat contracted. The blood-vessels of the conjunctiva are generally somewhat injected in persons who are well nourished and not deficient in blood. It is in this degree of narcotism that rigidity and spasms of the muscles are met with in certain cases. In the fourth degree of narcotism the breathing is stertorous, the pupils dilated, and the muscles completely relaxed. It is seldom necessary to carry the effects of chloroform so far as this degree. As the effects of the vapour subside the patient passes through the different degrees of its influence, in the inverse order to that in which they were induced.

There is often a considerable diminution of the common sensibility whilst the patient still retains his consciousness, especially when the chloroform is inhaled slowly, but it very rarely happens that even a trifling surgical operation can be performed without pain, unless unconsciousness is induced. Accordingly it is almost the universal practice, when this agent is used, to induce a state of unconsciousness before attempting to operate ; and to do otherwise would generally lead to failure. During the recovery of the patient who has been unconscious, there is, however, frequently a greater amount of anæsthesia than at the commencement of inhalation, and the tying of vessels and introduction of sutures may sometimes take place at the concluding part of an operation, whilst the patient is awake, without his feeling what is being done.

There is generally a considerable amount of anæsthesia in the second degree of narcotism. The loss of sensation is indeed sometimes so complete in this degree, especially in children, that the surgeon's knife may be used without pain, and I have seen a child unconsciously handle its toys all the time it was undergoing the operation of lithotomy. Commonly, however, the use of the knife, when the narcotism has not proceeded further than this degree, occasions expressions indicative of pain, which are either not remembered, or are recollected as having occurred in a dream. The patient is usually in the second degree of the effects of chloroform during the greater part of the time occupied in a protracted operation ; for although it is necessary, in most cases, to induce a further amount of narcotism before the operation is commenced, it is not usually necessary to maintain it at a point beyond this.

In the third degree of narcotism there is never any perception or consciousness of pain, but anæsthesia, in the proper sense of the term, is not a necessary part of this degree of narcotism when it is first induced, and in some cases a patient may flinch, and put on an expression of countenance which seems indicative of pain. By continuing the inhalation gently for a minute or two, a state of complete anæsthesia can be induced in almost every case, without carrying the narcotism beyond this degree.

The patient is always perfectly insensible in the fourth degree of narcotism. It is sometimes necessary to carry the effects of chloroform as far as this degree, when the surgeon is dissecting in the neigh-

bourhood of important vessels and nerves, in certain robust persons, and others who have acquired an excess of sensibility by hard drinking, and who can scarcely be kept quiet under the knife, except when the breathing is stertorous.

The pulse is nearly always increased, both in force and frequency, during the early part of the inhalation of chloroform, but after the patient has become quite insensible, it generally settles down nearly to the natural standard ; and in the middle of the greatest operations it is often beating with ordinary volume and strength not more than sixty times in a minute. The pulse rarely becomes weaker or slower than natural, except from considerable loss of blood, or when the patient is about to be sick.

The age of the patient has some influence in modifying the effects of chloroform. This agent acts very favourably on children, and does not cause the rigidity and struggling, after the loss of consciousness, which are sometimes met with in the adult ; and absence of feeling is generally induced with less narcotism of the nervous centres than in grown-up persons. The effects of the vapour are more quickly produced and also subside more quickly in children than in adults, owing to their quicker breathing and circulation. Frequently, however, when the insensibility has been kept up for twenty minutes or half an hour, in a child, it is followed by a natural sleep of some hours duration, if there is no painful wound or other cause to prevent the sleep. The writer of this has given chloroform in a few cases as early as the ages of eight or ten days, and to 200 infants under a year old. In persons advanced in years the effects of the chloroform generally subside rather slowly, owing, no doubt, to the slower breathing and circulation.

The comparative strength or debility of the patient has considerable influence on the way in which chloroform acts. The more feeble the patient is, whether from illness or any other cause, the more quietly does he usually become insensible ; whilst in the strong and robust there is frequently mental excitement in the second degree, and rigidity of the muscles and struggling in the third degree of narcotism. Patients in a state of debility resemble children in coming quietly and easily under the influence of chloroform, and also in the circumstance that the common sensibility is suspended with less oppression of the nervous centres than in robust persons. Children and persons in a state of debility have usually an acute sensibility, which causes them to suffer pain from very slight causes ; but this sensibility is more easily suspended by chloroform and similar agents than the less acute sensibility of robust persons.

Patients who are subject to hysteria sometimes have symptoms of the complaint, such as laughing, crying, or sobbing, as soon as consciousness is suspended, or even impaired, by the chloroform ; but these symptoms can always be subdued by continuing the inhalation.

Chloroform occasionally brings on a fit of epilepsy in persons who are subject to this disease. In the few cases in which epileptic convulsions are caused by this agent, they do not appear till the third degree of narcotism is induced, differing in this respect from hysteria, which comes on in the second degree, or even earlier. The course to pursue when epileptic convulsions appear, is to

continue the chloroform gently and steadily till they subside. The writer has never known the chloroform fail to subdue the convulsions in a very few minutes, and he has never seen them recur after the operation, as the effects of the vapour were subsiding.

Chloroform has often been administered to prevent the pain of surgical operations at all the periods of pregnancy, and no ill effects have been known to arise from its use in this way. The writer has exhibited it in several cases for the removal of large tumors, and other important operations during pregnancy, as well as in tooth drawing and other minor operations. One case of abortion has been related, which occurred in America, after its use; but in that instance it was inhaled very largely, for toothache, without medical advice. It is customary to avoid the menstrual period in fixing the time for any surgical operation which admits of delay, but when it cannot be so arranged, there is no objection to the inhalation of chloroform during menstruation. There is, however, a little more tendency to slight hysterical symptoms during its inhalation at this period than when the same patients inhale it at other times.

Phthisis and bronchitis sometimes cause a little difficulty and delay in the administration of chloroform, as the vapour is liable to excite coughing when the mucous membrane of the air passages is irritable. The inconvenience is, however, confined to the time of inhalation, and the cough is generally relieved afterwards; indeed, chloroform has often been inhaled with advantage to relieve the cough in consumption, so that there is no possible objection to its use in cases where it is found requisite that the consumptive patient should undergo a surgical operation.

With regard to the employment of chloroform in cases where there is disease of the heart, the surgeon should bear in mind that the question is not strictly between using chloroform and not using it, but between this agent and the pain of the operation. The pulse often increases to more than twice its natural frequency during the performance of even trifling operations in the waking state, and the patient often strains and holds his breath till the action of the heart is extremely irregular and intermittent, from the impeded passage of blood through the lungs. These effects of pain appear much more likely to arrest the action of the heart, when embarrassed by valvular disease or weakened by fatty degeneration, than does the action of chloroform, when carefully administered and not continued too long. Fatty degeneration of the heart has, indeed, been present in a few of the deaths from chloroform, but this affection is so common, that it has probably been present in quite as great proportion of the patients who have inhaled chloroform with impunity, as in those who died from its effects. The only patient whom the writer has lost whilst inhaling this agent, was, indeed, a gentleman of seventy-three, with extreme fatty degeneration of the heart, the symptoms of which were very evident during life; but it is probable, from the manner in which this patient died, that the disease of the heart was the sole cause of the sudden death; and the writer has not been deterred from administering chloroform during surgical operations in numerous other cases in which the symptoms of fatty degeneration of the heart were present in a very marked degree.

Diseases of the brain do not prevent the administration of chloroform. The writer has given it to several patients who had suffered from a previous attack of apoplexy. In some of these cases the paralysis resulting from the attack still remained, but the chloroform was not attended or followed by any ill effects. Chloroform is often of signal service in the cases of insane patients who require a surgical operation, as it enables the surgeon to perform operations that he could not accomplish without its aid. The vapour, however, can sometimes be administered to insane patients only by force, as they cannot always be persuaded to breathe it voluntarily.

It was at one time asserted that persons addicted to hard drinking were with difficulty rendered insensible by chloroform or sulphuric ether, but the writer has always found that these persons were rendered unconscious, and even comatose, by the same amount of these agents as other patients; sometimes, however, hard drinkers of spirituous and fermented liquors have a morbid excess of sensibility in the nerves of common sensation, and do not lie still under the use of the knife, except when the brain is deeply narcotised and the breathing almost stertorous.

The only direction which it is usually requisite to give beforehand to the patient who is about to inhale chloroform is, to avoid taking a meal previous to the inhalation. It is not desirable, however, that he should fast beyond his usual hour of taking food. The best time for an operation under chloroform is before the patient's usual breakfast time, when this can be arranged. It answers very well, however, to perform the operation about the time when the patient would be ready for another meal, or if the time of the operation fall two or three hours after the usual time of eating, to request him to take only a slender repast at that time, so as merely to prevent the feeling of hunger. These precautions are intended to prevent, as far as possible, the vomiting which not unfrequently follows the use of chloroform, and constitutes an unpleasantness and inconvenience which it is desirable to avoid.

The patient who is about to inhale chloroform is sometimes in a state of alarm, either about that agent itself, or the operation which calls for its employment. It is desirable to allay the fears of the patient, if possible, before he begins to inhale, as he will then be able to breathe in a more tranquil and regular manner. In some cases, however, the apprehensions of the patient cannot be removed, and they subside only as he becomes unconscious from the inhalation. It has been said that chloroform ought not to be administered if the patient is very much afraid, as the fear would make the chloroform dangerous; but this is a mistake, the danger, if any, lies in the fear itself. Patients have been known to die of fear alone, before the discovery of inhalation for the prevention of pain; and two patients died in a sudden manner, apparently from fear, just as they were commencing to inhale chloroform, and before they got under its influence; but it is probable that if they had lived till the chloroform had taken effect, they would have been as safe as other patients who have inhaled it. Fear and chloroform are each of them capable of causing death, but it seems impossible that they should combine to cause danger when the chloroform is administered with the usual precautions, so as

gradually to remove consciousness. Fear is an affection of the mind, and can no longer exist when the patient is unconscious; and the action of that amount of chloroform which is consistent with even disordered consciousness is stimulating, and increases the force and frequency of the pulse, in the same way as alcohol, and is therefore calculated to counteract the effects of fear whilst it lasts; and when the chloroform has been absorbed in sufficient quantity to cause unconsciousness, fear subsides, and with the fear, its effects on the circulation. It is a subject of constant observation by the writer, that the pulse, which is extremely frequent in many patients from apprehension, when they begin to inhale, settles down to its natural pace as soon as they become unconscious. If anæsthetics were refused the patients who are much afraid, the timid and feeble, who most require them, would often be deprived of their benefits. Moreover, they would either be prevented from having the advantage of surgery, or they would be subjected to the still greater fear of pain, as well as the pain itself; for whatever fears a patient may have when the moment comes for inhaling a narcotic vapour, he has only chosen to breathe it on account of a still greater fear of pain.

The most convenient position in which the patient can be placed whilst taking chloroform is lying on his back or side, as he is then properly supported in the state of insensibility, and can be more easily restrained if he should struggle whilst becoming insensible. The half recumbent posture on a sofa answers very well, and the patient may be seated, when that is most convenient to the operator; he must, however, be placed in a large easy chair with a high back, so that the head as well as the body may be well supported, otherwise he would be apt to slide or fall when insensible. If faintness should come on, the patient must of course be moved into the horizontal position, as under any other circumstances.

Judging from experiments on the lower animals, the quantity of chloroform which requires to be absorbed to cause insensibility is such that, in the adult human subject of average size and strength, there is about eighteen minims of this liquid in the system during an operation, without pain; but as a good deal is dissipated in all the usual methods of inhalation without being absorbed, a much larger quantity than this is used in making a patient insensible. The chloroform also keeps exhaling from the lungs of the patient all the time he is under its influence, as can be proved by chemical tests, and must be replaced by the inhalation of a little at a time, during the course of an operation. About four cubic inches of vapour of chloroform in one hundred cubic inches of air, are the most suitable proportions for causing insensibility during surgical operations. A cubic inch and a half of vapour in each hundred cubic inches of air is, indeed, capable of causing insensibility, but an inconvenient length of time is occupied when the vapour is so much diluted, whilst, on the other hand, if the air breathed by the patient contains eight per cent. of vapour, or upwards, it is liable to act with dangerous, and even fatal, rapidity.

The great point to be attended to in the administration of any narcotic vapour, is to present to the patient such a mixture of vapour and air as will produce its effects gradually, and enable the medical man to stop at the right point. Al-

though four per cent. of vapour is the most suitable proportion in the case of chloroform, the quantity may vary from a little more than two per cent. up to about six per cent., without inconvenience or danger, so that the process of inhalation need not be one of mathematical exactitude. A great number of apparatus have been used in the administration of chloroform. That which the writer has employed for ten years is made of metal, and consists of a double cylinder, the outer space of which contains cold water, to regulate the evaporation of the chloroform. The inner part of the cylinder is furnished with two coils of stout bibulous paper, to afford a surface, wetted with chloroform, over which the air passes before being inhaled. The quantity of vapour which the air takes up can be ascertained by weighing the apparatus with some chloroform in it, before and after passing a measured quantity of air through it; and the extent of surface of bibulous paper can be altered at different times of the year, according to the temperature of the season. This apparatus is attached by a wide elastic tube to a face-piece, which admits of unimpeded respiration by either the mouth or the nostrils, and is furnished with a valve, by which any amount of additional air can be admitted to dilute still further that which has passed through the inhaler and become charged with vapour.

A pocket handkerchief folded and made into the form of a cone, as recommended by Dr. Simpson, is an apparatus which is very convenient, and has the merit of being always ready; and a good sized hollow sponge is also equally convenient. This method of giving chloroform is, however, open to the objection, that the proportions of vapour and air which the patient breathes cannot be properly regulated; and the objection is still greater from the circumstance that those who advocate this mode of administering chloroform proceed on the supposition that there is no occasion to regulate the proportions of vapour and air; that, in fact, it is only requisite to let the patient have sufficient air for the purposes of respiration, and enough chloroform to cause insensibility, and all will be right. The truth is, however, that if there be too much vapour of chloroform in the air the patient breathes, it may cause sudden death, even without previous insensibility, and whilst the blood in the lungs is of a florid colour. The table in the earlier part of this article shows that the air is capable of taking up a much greater quantity of vapour of chloroform at ordinary temperatures than it would be safe to inhale; and although the air does not get quite saturated with vapour of chloroform in passing over a handkerchief, yet, on many occasions, so much vapour has become mixed with the air, as to cause sudden death, without any previous warning from the symptoms.

Whenever chloroform is administered from a handkerchief or sponge, it should be diluted with one or two parts by measure of spirits of wine, or eau de Cologne. In this way the convenience of the handkerchief or sponge can be taken advantage of without the danger. Very little of the spirit is inhaled, as the greater part remains behind after the chloroform has evaporated; but it acts by lowering the elastic force of the vapour of chloroform, and diminishing the amount of vapour which is given off from the handkerchief or sponge, just as diluting a strong solution of ammonia with ad-

ditional water diminishes the amount of the volatile alkali, which escapes as gas. One hundred cubic inches of air are capable of taking up fourteen cubic inches of vapour, at 60°, from pure chloroform, and becoming expanded to 114 cubic inches; but when the chloroform is diluted with an equal volume of alcohol, it will only yield eight cubic inches of vapour to 100 of air. In passing over a sponge or handkerchief the air would take up less than this, usually four or five per cent., which is a quantity sufficient to cause insensibility in four or five minutes, without the risk of sudden accident. It is not desirable to dilute the chloroform with spirit when it is administered with any kind of apparatus which is intended to regulate, with any approach to accuracy, the amount of vapour in the air which the patient breathes, for the chloroform evaporates from the spirit in greatest quantity at first, and less afterwards, as the remaining spirit contains less and less chloroform. This circumstance forms no objection, however, to diluting chloroform with spirit when it is to be inhaled from a handkerchief or sponge, as no great accuracy is aimed at by this method, and patients may be made insensible by these means with as much regularity when the chloroform is diluted as when it is not. Two drachms of the mixture of chloroform and spirit may be poured in the handkerchief or sponge at one time.

Whatever means are used in the exhibition of chloroform, or any other narcotic vapour, the patient should have the liberty of breathing either by the nostrils or mouth. There should be no tube in the mouth, nor any nose-clasp employed. When he begins to inhale, it is advisable to request him to breathe gently and quietly, in other words, to do nothing but conduct himself as if he were about to fall asleep naturally; for if he breathes deeply, the vapour feels much more pungent than it otherwise would do, and is apt to excite coughing, or a feeling of suffocation. It is desirable also to give the vapour in a very diluted state for a minute or so at first, in order that the air passages may get gradually accustomed to its presence. This is more particularly desirable in children and timid persons. It can be effected by means of the moveable valve in the face-piece of the inhaler which is used by the writer; or when a handkerchief or sponge is employed, by holding it at first some little distance from the face, and then gradually approaching it nearer, so that more and more of the air which the patient is to breathe passes over the surface moistened with the anæsthetic agent.

Some patients become excited as soon as they are unconscious, and attempt to get up, or to push away the chloroform; under these circumstances, if they cannot be calmed by what is said to them, they should be held, and the vapour should be gently and steadily continued for a minute or two, till a state of quietude is produced. The patient generally remains quiet as he becomes unconscious, but there is no difficulty in ascertaining whether he is conscious or not: if the eyelids remain open, the countenance shows whether the patient is conscious or not: and if they are closed it is only necessary to touch them gently in order to ascertain this circumstance. If he is still conscious, he will look at his medical man, and probably speak, or, at all events, show by his countenance that he is awake.

The absence of consciousness and a state of quietude are both requisite before the commence-

ment of a surgical operation, and they go a good way towards the preparation of a patient for it, but these symptoms may be present and the patient not be ready for the operation. It is necessary to know whether he will lie still under the use of the knife, or whether he will make a resistance and an outcry, which he would probably not make if he were awake. The best plan to ascertain when the patient is ready for an operation, is to raise his eyelid gently, by placing one finger just below the eyebrow, and then to touch its ciliary border very gently with another finger. This should not be done roughly, nor too frequently, for fear of exhausting the sensibility when it is weak. Just after unconsciousness is induced, the eyelids are often closed very strongly when their margins are touched, and there seems to be a real hyperæsthesia; but this is probably only apparent, and arises from the control of the will being removed, whilst sensibility remains. By continuing the chloroform, the sensibility of the margins of the eyelids is diminished, until they may be touched without causing winking. Under these circumstances the most severe operations may, with scarcely an exception, be commenced without sign of pain. This test even indicates the amount of sensibility where a little remains; when, for instance, touching the edges of the eyelids causes very languid and slight winking, the patient will usually flinch a little on the use of the knife, but only in a manner that can be easily restrained, and does not interfere with the greater number of operations. The only cases in which the indication afforded by the sensibility of the eyelids is not always to be depended on, are those of certain hysterical patients, in whom there is occasionally no winking on the eyelids being touched, even when unconsciousness is scarcely induced. In these cases, one must be guided by the other symptoms, and also by the length of time the inhalation has continued, the strength of the vapour, and the depth and frequency of the breathing. Indeed these circumstances should be observed in every case, and all the symptoms should be watched, such as the expression of the face, the state of the breathing, and the condition of the limbs with respect to their tension or relaxation.

The condition of the breathing affords one of the best indications that the inhalation is proceeding further than is desirable, and this is fortunately a sign that cannot be overlooked by the person who is giving chloroform. Whenever the breathing becomes stertorous the inhalation should be immediately suspended. Under these circumstances the patient is always insensible, and indeed it is seldom requisite to carry the effects of the vapour so far that stertor is produced. It sometimes happens, when a little more chloroform has been inhaled than is necessary, that the patient breathes for half a minute or so by the diaphragm only. The abdomen rises and falls freely, but, as the muscles of the chest do not fix the ribs, hardly any air enters the lungs, and the face becomes rather livid; the pulse meanwhile goes on very well; and at last the patient takes a deep, sonorous inspiration, when the face resumes its proper colour, and the breathing goes on as usual. When this state of breathing occurs, it usually takes place a few seconds after the inhalation has been discontinued, and arises from the accumulation of the effects of the chloroform, owing to the

absorption of the vapour which was contained in the lungs at the time when the inhalation was left off. This increase, or accumulation, of the effects of chloroform lasts for about twenty seconds; it is not dangerous unless the vapour is inhaled of too great strength, but it should always be borne in mind. It may be prevented by reducing the strength of the vapour just as the patient is getting insensible.

When rigidity and struggling occur in the third degree of narcotism, that is just after the suspension of consciousness, the inhalation should be continued gently till these symptoms are subdued. The patient is sometimes insensible before the rigidity is overcome, but it is necessary to have him in a state of quietude, in order to enable the surgeon to operate with convenience and safety. It is advisable to proceed cautiously and slowly when rigidity and struggling are present, because, when these symptoms occur, the patient has already absorbed nearly the usual quantity of chloroform, and he sometimes holds his breath, and then suddenly takes a deep inspiration, when he might inhale an overdose of the vapour, unless it were exhibited to him in a well diluted state. In very robust men, accustomed to great muscular exertion, it sometimes takes five or six minutes before the rigidity can be fairly subdued. If the operator should be afraid to proceed with the exhibition of chloroform on account of the violence of the muscular spasm and rigidity, the inhalation may be resumed after it has been discontinued for a few minutes, and the above symptoms will be less violent than at first. After the muscular spasm and rigidity are subdued by the chloroform, they rarely recur during the operation.

The pupils are usually somewhat contracted in the third degree of narcotism, when the eyes are inclined upwards, and they seem to be less sensitive to light when the patient is under the influence of chloroform than at other times. They do not become totally insensible to light, or widely dilated, except by such a deep effect of the chloroform as it is desirable to avoid.

There is often an increased flow of saliva during the inhalation of chloroform, and although this seldom causes any impediment, the patient occasionally makes efforts of deglutition, which retard the inhalation; and, at other times, he holds his breath, with his mouth full of saliva after he is unconscious, as if he had some obscure idea of disposing of it in a suitable manner. If a towel is placed against the lips under these circumstances, he generally empties his mouth, and goes on breathing properly.

The length of time which it is most desirable to occupy in the exhibition of chloroform, before an operation is commenced, is about two minutes in infants, three minutes in children, and four or five minutes in adults. Circumstances occasionally occur to lengthen these periods, but it hardly ever takes more than seven or eight minutes to render the patient sufficiently insensible. When a longer time has been occupied there has always been a physical cause for it. The writer has never had any reason to attribute the delay to any idiosyncrasy, or peculiarity in the patient, but merely to the circumstance that the vapour did not enter the lungs in sufficient quantity within a given time. He has had under his care several patients, who, it was supposed, were not susceptible of the

effects of chloroform, or were, at least, very difficult to bring under its influence, as previous attempts had failed; but he met with no difficulty in causing insensibility in any of these cases.

If the operation be of short duration, the first application of chloroform will often suffice without repeating the inhalation. The patient now and then remains insensible to the knife for three minutes after the inhalation is left off, but this is an exception; and one cannot make sure of this prolonged effect of chloroform without producing a deeper state of narcotism than is desirable. When the operation lasts more than a minute or two, it is usually necessary to repeat the inhalation; and indeed it is generally advisable to let the patient have a few inspirations of air mixed with vapour of chloroform about every half minute whilst the operation lasts, in order to keep up the insensibility. When the surgeon is operating in the neighbourhood of important parts, it is desirable to prevent any sign of sensibility, and to keep repeating the chloroform so as to keep up the coma, without, however, causing dilatation of the pupil, or embarrassment of the breathing; but in the greater number of operations, it is better to wait till there is some sign of sensibility, such as a slight cry or tendency to flinch, before resuming the inhalation; and then a few inspirations of well diluted vapour make the patient quiet again.

Consciousness usually returns within five minutes after the inhalation has been discontinued. After a brief inhalation, for a very short operation, the patient sometimes becomes conscious almost immediately; whilst, after a protracted operation, ten minutes sometimes elapse before the recovery of consciousness. When left to himself the patient usually recovers from the effects of the chloroform in a very tranquil manner, and it is desirable not to talk to him until he has completely recovered. If he has not been moved whilst insensible, but wakes in the position in which he fell asleep, he very frequently supposes that he has not been asleep at all, and in a number of instances will contend, even after a prolonged operation, that the chloroform has not taken effect. Of course he soon finds out his error. After the greater number of operations the patients have to remain in bed; and even after minor operations under chloroform it is advisable that the patient should lie, or at least sit still for half an hour, or longer, before making any bodily or mental exertion.

There are occasional sequelæ of the inhalation of chloroform. Sickness is the most important of these. It is most frequent when the inhalation takes place soon after a meal, but the best directions with regard to diet will not always prevent it, as the food is sometimes not digested when the patient is expecting a surgical operation, and the breakfast may be vomited in an unaltered state after the lapse of several hours. Moreover, there may be sickness and retching when there is nothing in the stomach. Moving the patient, as the effects of the chloroform are subsiding, is very liable to excite vomiting when it might not otherwise occur; it is therefore advisable to allow the patient to lie for about half an hour, when convenient, without moving his head from the pillow. Even when a feeling of sickness is present it often subsides, by this means, without the occurrence of vomiting. It is desirable also not to give anything to eat or drink till about an hour after the chloroform, and

generally not even then, unless there is an inclination for it. Even medicine, such as an opiate, is better delayed for an hour or so, except when there is an urgent necessity for giving it sooner. When a patient is faint from loss of blood of course this rule must be disregarded, and wine or brandy may be given, and repeated if it be vomited. When vomiting occurs, it most usually takes place after the chloroform is discontinued, and whilst its effects are passing off. It often occurs before the patient is quite conscious, and he does not know it unless he is told. In a few cases, in which there is a good deal of food in the stomach, vomiting comes on before the operation is concluded, and now and then even before it is commenced. When vomiting comes on during an operation, it is sometimes difficult to prevent the patient from awaking; but this can generally be accomplished by wiping the mouth, and resuming the inhalation as soon as the effort of vomiting is over. In many cases the sickness does not come on till the patient awakes, but the sickness really due to chloroform probably always begins within an hour or two, or, at the furthest, just after the first food which is taken. When sickness did not occur till the following day the writer has always found that an opiate had been taken, or, at least, that there was some other cause to which it was probably due. Several cases have occurred in which the sickness has lasted for two or three days in spite of the usual remedies; but these cases form a small portion of the whole number in which chloroform is administered, and they have chiefly happened in persons who were subject to attacks of vomiting from slight causes.

The sickness caused by chloroform usually subsides as soon as the stomach is emptied by vomiting. It is therefore advisable not to do anything for it for an hour or so; but when it continues beyond this period a little cold brandy and water removes it in most cases. When this remedy has failed, a dose of opium has been found to relieve the sickness. Effervescing draughts have not appeared to be of much service, and draughts of warm water seem to make the sickness worse. It is not advisable for the patient to make any effort, but only to vomit if obliged to do so.

Chloroform is occasionally followed by faintness and depression, especially if the patient remains in the sitting posture, and is liable to faintness at other times. The horizontal position is the treatment for this, with ammonia to the nostrils and wine or brandy if the faintness does not presently subside.

Hysterical symptoms sometimes come on in female patients as the effects of chloroform are subsiding, and the writer has on two occasions met with them in the male. These symptoms nearly always pass off spontaneously within half an hour. If they do not, they must be treated on the ordinary principles. Hysteria was probably quite as frequent and severe an attendant on operations when they had to be submitted to without the aid of anæsthetics as at present.

If chloroform, when administered in the usual way, were continued in the disregard of the symptoms death would undoubtedly be the result; and some persons who have lost their lives by incautiously inhaling it, when no one was near to watch its effects, have probably expired from its being continued too long; but on examining the details

of the recorded deaths from chloroform, during its administration for surgical operations, it will be found that, in every case, the dangerous symptoms, if not the actual death of the patient, came on suddenly, and without previous warning. There is in fact no reason to conclude that any of these accidents occurred from mistaking, or overlooking, the symptoms which indicate that it should be left off, when it is administered throughout in a safe and gradual manner.

Experiments on dogs, cats, and other domestic animals, show that chloroform may cause death in two very distinct modes; and as these animals are acted on by chloroform precisely in the same way as the human being, in all those stages and degrees of its influence which can be induced without danger, it may safely be concluded that, when they are killed in such a manner that the mode of dying exactly resembles that which occurs in the accidents to the human subject, the precise cause of death is the same. When animals are made to breathe air containing four or five per cent. of its volume of vapour of chloroform until they are killed, death takes place slowly and gradually. They first become gradually insensible, and then deeply so; afterwards the breathing becomes embarrassed, and it ceases fifteen or twenty minutes after the beginning of the experiment. The heart continues to beat very distinctly for one or two, and sometimes three minutes after the breathing has ceased; and its action becomes suspended, as in asphyxia, by privation of air, on account of the absence of the respiration, and not from the direct action of the chloroform. During this interval, whilst the heart is still beating, the animal can be easily restored by artificial respiration, and, moreover, there are often two or three gasping inspirations at the moment when the heart is ceasing to beat, which generally have the effect of restoring its action, and bringing about the recovery of the animal, if the chloroform have been withdrawn.

When, on the contrary, the animals mentioned above are made to breathe air containing eight or ten per cent., or upwards, of chloroform, death takes place, in nearly all cases, very suddenly, and the action of the heart does not survive the breathing. The chloroform is absorbed into the blood as it passes through the lungs, in such quantity that it acts directly on the heart, which ceases to beat at the same moment as the breathing ceases, or, in a few cases, even before the breathing.

It is by this last of the two modes of death that the accidents from chloroform have occurred. In no recorded instance has the pulse survived the respiration, whilst in several cases it has ceased before the breathing; and as regards the strength of the vapour which was being inhaled just before the accidents happened, it may in every case have been as much as eight or ten per cent. in proportion to the air. Attention has rarely, if ever, been directed to this point in cases in which accidents have occurred, although great care and attention have been generally employed. Many of the deaths from chloroform took place before the operation was begun, several during its performance, and a few just when it was completed. In some of the accidents which occurred within the first two or three years after chloroform was introduced the patients died suddenly, within half a minute after commencing to inhale, having taken only a few inspirations.

There was disease of vital organs in a few of the patients who died from chloroform, but, on the whole, they were probably in as sound and healthy a condition as the multitude who have inhaled this agent without ill effects. Not a few of them certainly were robust young men suffering only from a local ailment or injury. This shows that the accidents cannot be attributed to the condition of the patient. Some hidden peculiarity of constitution has indeed been occasionally alluded to as a probable cause of the accidents, but there is an answer to this in the circumstance that many of the same patients had inhaled chloroform previously without ill effects, some of them within two or three days of the time of the accident. In no case can death be attributed to any impurity in the chloroform employed.

The appearances found in the body after death from chloroform are not very striking. The head has generally presented nothing peculiar. The lungs have usually been somewhat congested, and in some cases very much so. The quantity of blood in the cavities of the heart has varied very much, probably from its being disturbed by the artificial respiration nearly always employed; for in animals killed by chloroform, the right cavities of the heart are always full of blood, and the left cavities generally contain a small quantity. The blood has in nearly all cases remained fluid after death, as it usually does in cases of sudden death from any cause in the human subject. A good deal of stress has in some cases been laid on this fluidity of the blood after death from chloroform, but there is one circumstance which shows that it is not connected with the mode of dying as a cause, but only as a consequence. If the heart or great vessels of an animal are cut just after it is dead from chloroform, the blood which escapes always coagulates immediately and firmly, but if the body is not opened till the following day, the blood is found almost altogether fluid, and remains so.

The first rule to be observed, in order to avoid the danger of accident in administering chloroform, is to have the vapour always sufficiently diluted with air, to so regulate the process, in fact, that the vapour never constitutes more than six per cent. of the inspired air. The means of effecting this have been already detailed. The next rule is to attend closely to the symptoms which have been above described, and stop whenever insensibility is induced, or when the breathing has any tendency to become stertorous. When the first rule is followed the second is easy enough; but if the air the patient breathes should become too highly charged with vapour, it may happen that no amount of attention to the symptoms will avert an accident. In several fatal cases, which occurred whilst the patient was carefully watched, the last beat of the pulse was equal in volume and force to those which preceded it.

The great necessity of avoiding accidents with chloroform is rendered the more urgent by the circumstance that so little can be done to remedy an accident when it occurs. If the patient is in real jeopardy from chloroform he nearly always recovers spontaneously and immediately, or not at all. Only one or two instances are known of patients being restored from the effects of an overdose of chloroform, who would not probably have recovered of themselves. Artificial respiration promptly and vigorously applied, affords the best

chance of restoring the patient; and it should be resorted to as soon as the pulse and natural breathing have ceased. Probably the postural method, introduced by the late Dr. Marshall Hall, is the most ready and effectual. The writer has been able to restore animals by artificial respiration, in some cases where they evidently would not have recovered without it, but only when a tube had been fixed in the trachea previously to giving the last dose of chloroform, so that the artificial respiration might be effectually performed within a quarter of a minute after apparent death. In these trials the action of the heart recommenced in a few seconds, or not at all. The jugular vein might with propriety be opened if it were distended; for in opening animals just after they were suddenly killed by chloroform, the action of the heart has, in some instances, recommenced on the distension of its right cavities being relieved by cutting the veins at the root of the neck. The writer has not found electro-magnetism of any use in the restoration of animals which were killed by chloroform. As to the dashing cold water on the patient, applying ammonia to the nostrils, and such like measures, it is enough to say that they would have no effect whatever, even in a case where the patient has inhaled chloroform within perfectly safe bounds, and is in a state to undergo even a minor surgical operation without flinching.

The proportion which the number of accidents from chloroform bears to the whole number who inhale it cannot be ascertained; for although cases of accident are generally published, the number who inhale it without injury is unknown. It is certain, however, that the proportion of the accidents from its use is extremely small. The remark is sometimes made, that patients used occasionally to die suddenly, just at the beginning of a surgical operation, apparently without any adequate cause. Whether these cases were as numerous as the deaths from chloroform might be the subject of ingenious speculation, for there is no means of determining; there is, however, no reason to suppose that the deaths which occur under the use of chloroform are of the same nature, and happen to the same persons, as the deaths alluded to. These latter probably arose from the effects of mental emotion or of pain, both of which are prevented by chloroform; and the endeavour of the medical man should be, to prevent, as far as possible, both the dangers of pain and mental emotion, and also those which are peculiar to chloroform.

Sulphuric ether continues to be still used in some parts of America and the continent of Europe. The chief objection to it is its strong and persistent odour, which remains in the breath of the patient frequently for two days. The surgeon also carries the odour of it about with him. The effects of sulphuric ether are as nearly as possible the same as those of chloroform, but a much larger quantity requires to be inhaled. Whilst less than a fluid drachm of chloroform usually suffices to make the adult patient insensible, about a fluid ounce of ether is required; and unless means are taken to counteract the cold produced by the evaporation of the ether, the evaporation itself often becomes so diminished, that a long time is occupied in causing insensibility; and in some cases, no effect is produced beyond a state of excitement, as the patient goes on breathing air cooled much below the freez-

ing point, but containing very little vapour. By using a copious bath of cold water to supply the caloric carried off by the evaporation of the ether, the writer was able to make every patient insensible with this agent, and generally in the space of four minutes. The recovery from the effects of ether is generally slower than from those of chloroform, and the patient often remains in a state of inebriation for about half an hour after it. Sulphuric ether has, perhaps, but one advantage over chloroform, which is, however, an important one—it is its great safety. There is reason to conclude from experiments on animals, that this agent is altogether incapable of causing sudden accidents, such as those which have happened in the employment of chloroform. Only two deaths are known to have occurred during the inhalation of ether. They both took place in France. In one case the patient appeared to die slowly from want of air, owing to the faulty construction of the inhaler. The other death occurred suddenly, during the removal of a tumor of the upper jaw, in a very unfavourable subject, and was probably caused by loss of blood.

The writer of this article has employed amylene in between two and three hundred operations, but has discontinued it on account of two accidents which he met with. Amylene was discovered by M. Balard in 1844. It is made by distilling amylic alcohol, *i. e.* purified fusel oil, with chloride of zinc. It is a colourless and very mobile liquid, only two thirds as heavy as water, and less than half the weight of chloroform. It is composed of ten atoms carbon, and ten atoms hydrogen. It boils at 102° Fahr., and the specific gravity of its vapour is 2.45. Its solubility in water is curiously slight, as it requires about 10,000 parts of water for its solution. It has an odour somewhat resembling that of naphtha, not so strong or permanent as that of sulphuric ether, but stronger and more permanent than that of chloroform. It is almost without taste or pungency. The amount of amylene used in making an adult patient insensible is about half a fluid ounce, and is, consequently, intermediate between those of chloroform and ether. In a long operation, indeed, the amylene has to be repeated so frequently that a larger quantity is used than in the case of sulphuric ether. With the exception of the accidents alluded to above, the action of amylene was extremely favourable, and it appeared to possess certain advantages over chloroform in the following circumstances:—first, its vapour being almost altogether without pungency, it was easier to breathe; second, the operation could be performed with a less amount of narcotism of the brain than in the case of chloroform or ether. In the operations under amylene the patient was usually in an apparently waking state, though really unconscious of what was occurring around, and occupied with his dreams. In a few cases he was conscious, and even talked to his surgeon during the operation. Third, the recovery was more prompt even than after chloroform; and fourth, sickness was extremely rare after amylene.

Amylene does not cause insensibility unless the air which the patient breathes contains as much as fifteen per cent. of the vapour, and judging from experiments on animals, the vapour may be increased to thirty per cent. without danger. When administered on a handkerchief or sponge, it is pro-

bably attended with as little or even less danger than undiluted chloroform. It has been largely used in Paris, Strasbourg, Berlin, and Lyons, without any accidents from its use being recorded. In the two cases in which death occurred during its use, the heart suddenly ceased to beat when the patients were not very insensible. The breathing continued in one case for ten minutes afterwards, and in the other case for even a much longer period. The means which the writer employed for the exhibition of amylene were the same which he has found so successful in the employment of chloroform. If he should use amylene again, he would be inclined to give it from a large bladder or bag, so that the quantity of vapour in the air might be under complete control.

Several agents have been inhaled with success, in a few cases, for preventing the pain of operations, besides those treated of above, but as they have not come into general use, it is unnecessary to enumerate them in a work on surgery.

The process of administering an anæsthetic vapour is so much the same in every case where severe pain is to be prevented, that very little requires to be said respecting particular operations. It is desirable, as a general rule, that the patient should be placed, before inhaling, in the position in which the operation will be performed, so that the surgeon will be able to commence without delay, as soon as insensibility is induced. In operations on the back, however, the patient should inhale first, and be turned over afterwards; and in cases where moving him causes great pain, he may inhale in bed, and be moved when insensible. In lithotomy the patient should be placed on the table, with a pillow under his head, and inhale till he is insensible. The sound may then be introduced, and afterwards the bandages should be applied, and the patient be drawn down to the foot of the operating table, a little more vapour being administered whilst this is done, to keep up the insensibility. In lithotomy in children, the feet and hands are sometimes not bandaged, but in this case the person administering the anæsthetic should hold the head or shoulders of the child with one hand, whilst the surgeon makes his first incision, otherwise the child may push its body away at this moment, unless the insensibility is deeper than is necessary; for the assistants who hold the legs, and think they are doing great service, make a fulcrum which enables the child to do this. In amputations, the tourniquet may with advantage be adjusted whilst the patient is inhaling, and tightened as soon as he is insensible. Operations on the anus and rectum obviously cannot be performed under chloroform or ether, whilst the patient is on his feet, and leaning over a bed or table; he must be placed either on his side with the knees drawn up, or else in the lithotomy position. Some patients have a great tendency to straighten out the legs during operations on the anus, unless they are made very deeply insensible, and in the cases of strong muscular men, it is desirable for the surgeon to have two assistants, as the great muscles of the lower extremities are with difficulty restrained, even if they retain but a third of their ordinary power.

In great operations on the face, such as the removal of tumors of the maxillary bones, there is often considerable difficulty in keeping up the insensibility during the operation; but by having

a hollow sponge in readiness, moistened with a mixture of chloroform and spirit, and holding it near the face whenever the hands of the operator and his assistants afford room, the patient can be rendered so far insensible that he does not remember the operation. The patient should not be made very deeply insensible in operations involving the mouth or nose, and accompanied with great bleeding. He may, however, be with safety made so insensible as not to have pain, provided all the facilities are given for getting rid of the blood that would be allowed in the waking state. The glottis retains its sensibility under the influence of anæsthetic agents if their effects are not carried to an extreme degree; but a patient when awake cannot breathe with more than a certain amount of blood in the fauces, therefore, as he cannot, when insensible, push away his surgeon and hold his head down, it must be held down occasionally, when the quantity of blood is such as to require it. A little blood is liable to get into the trachea in great operations about the mouth, whether the patient is insensible or not, and in either case it is coughed up again. There is no evidence of any harm having resulted from blood flowing into the windpipe in operations about the mouth. One patient died about an hour after the removal of the greater part of a tumor of the upper jaw and neighbouring bones, so much of it as could be reached; but his symptoms were those of exhaustion from loss of blood; and after death only a few small spots of blood were found in the lungs, and this small quantity apparently entered whilst he was moribund, for some hemorrhage continued to the time of death. Some of the blood is nearly always swallowed in operations about the mouth; this is generally the case in tooth drawing under the influence of chloroform, as is proved in the cases in which the patient afterwards vomits.

Chloroform and sulphuric ether are of great service in the reduction of dislocations, more particularly those of long standing; not only by the prevention of the pain, but by removing, or greatly diminishing, the resistance of the muscles. Some dislocations of the shoulder have been completely reduced, as long as five months after the accident, with the aid of these agents. There are other operations not unfrequently performed of late, under the influence of anæsthetics, which the surgeon could hardly have proposed without their aid; namely, the forcible breaking down of adhesions produced by disease of the joints. In a few cases also the operation for hernia has been prevented by the use of anæsthetics; the taxis having been successful under their use, after it had previously failed. Anæsthetic agents may be administered safely, and with great advantage, to patients who have to undergo operations in a state of great debility, either from disease or severe injury.

The local application of ice and salt, so much advocated by Dr. James Arnott, is capable of preventing the pain of those operations which do not go deeper than the skin. The ice should be well pounded and intimately mixed with the salt, then put into a piece of muslin, and applied to the part to be operated on. The effect is generally produced in from three to five minutes, and is known by the skin becoming very white and as firm as stearine. There is some pain during the application of the frigorific, and still more as the skin is recovering its sensibility, but this last can

be moderated by the application of iced water. When the operation extends to the tissues beneath the skin, pain is experienced.

It was not to be expected that the use of anæsthetic agents should make any great difference in the ultimate result of important operations. The fact of a multitude of patients inhaling these agents for minor operations, without ill effects, shows that they are not injurious to the health; and this being the case, the prevention of the pain of great operations cannot be otherwise than beneficial. The satisfactory condition in which a patient is generally found just after an operation without pain, confirms this view; at the same time it must be remembered that death was seldom due to the immediate effects of an operation before anæsthetics were employed, but to causes which came into action after the operation, and which are still in force. There are no very extensive or trustworthy statistics of the results, even of amputations, before the employment of anæsthetics, to compare with the present results of these operations, and if there were, it would be necessary to bear in mind that the very introduction of these agents has, in many cases, altered the conditions under which operations are performed. On the one hand, the patient often gives his consent to an operation at an earlier and more favourable period than he would do if he had to submit to the pain, and on the other, the surgeon sometimes recommends an operation when the prospect of success is so small that it would hardly counterbalance the evil of the pain, if that could not be prevented. The progress of surgery has also altered the circumstances under which operations are performed; resection of the larger joints being often performed now in cases where amputation would formerly have taken place. This change of practice is itself very much due to the introduction of anæsthetics. The most unexceptionable way of endeavouring to ascertain whether any, and if so, what influence has been exerted on the result of large operations by the use of anæsthetics, is to examine the result of these operations for a series of years in the same institution, before the use of these agents and afterwards. Dr. Fenwick made an extensive inquiry of this kind into the results of all the important operations in the Newcastle Infirmary, for a number of years before the use of ether and chloroform, and for the period during which these agents have been in use, and the comparison is, on the whole, decidedly in favour of the latter period.

The writer of this article has not kept an account of all the cases in which he has administered chloroform, but he finds, nevertheless, that he has memoranda of rather more than three thousand eight hundred surgical operations in which he has exhibited it. These have not been selected cases; on the other hand, whilst he has not declined to administer chloroform in any instance in which a surgical operation was required, he has been consulted in a great number of cases, and has undertaken to give this agent where other medical men had hesitated to do so, on account of disease of the heart, of great debility, or some other cause; for the writer has, after giving the subject his careful consideration, acted on the principle that chloroform, when carefully administered is, under all circumstances, less likely to be injurious than severe pain. With this amount and kind of practice the writer has lost but one patient whilst in-

haling chloroform, whom, he believes, as was previously stated, to have died of the disease of the heart under which he was labouring, and not from the anæsthetic; for the heart suddenly ceased to beat whilst he was making a straining effort, as if he were beginning to feel the operation—that of lithotrity. Every medical man who takes the same pains will of course be likely to have the same success as the writer; and, with the experience which has already been gained, it may reasonably be expected that accidents from the use of chloroform will be less likely than heretofore. There is every reason to conclude, therefore, that this agent may be administered with an amount of risk so small as to be hardly appreciable—less indeed than attends many of the most ordinary proceedings in medicine and surgery; and as severe pain is not without danger, it may not unreasonably be expected that chloroform may, in some cases, be an additional source of safety to the patient. The great and direct benefit of the prevention of pain by anæsthetics is so universally admitted, that it is unnecessary to do more than allude to it in this place; some instances have been mentioned above, in which these agents enable the surgeon to effect what otherwise could not be accomplished; and another advantage which they undoubtedly confer, is that of frequently causing patients to consent at once to receive the benefits of operative surgery, instead of withholding their consent, either altogether, or till the most favourable period for relief would be passed.]

John Snow, M.D.

ANEURISM, or ANEURYSM (from ἀνευρύσμα, a dilatation). The tumors which are formed by a preternatural dilatation of a part of an artery, as well as those swellings which are occasioned by a collection of arterial blood, effused in the cellular tissue, in consequence of a rupture, or wound of the coats of the artery, but having no outlet in the integuments (see *Guthrie, On Dis. of Arteries*, p. 40), receive the name of aneurisms. According to these opinions, aneurisms are of two kinds; the first being termed *true*, the second *spurious*, or *false*. Some modern writers reckon another form of aneurism, which is said to happen when the external coats of an artery being weakened by mechanical injury, or disease, the internal coat protrudes through the breach in the outer coat, so as to form a tumor distended with blood. This case has been denominated the *internal mixed aneurism*, or *aneurisma herniam arteriæ sistens*. The reality of this form of disease was believed in by Dr. W. Hunter; and some delicate experiments, instituted by Haller on the mesenteric arteries of frogs, appear to have been the first ground of the opinion.

However this may be with respect to the experiments made on certain animals, I am disposed to consider it fully proved by Mr. J. Hunter, Sir E. Home, and Professor Scarpa, that, in the human subject, an aneurism will not arise from the kind of weakness which is caused by cutting or even stripping off the external coat of a sound artery, whether the wound be closed or not.

[In the museum of the College of Surgeons there is a preparation, No. 1642, which is intended to illustrate this pathological condition. It is an aneurism of the upper part of the arch of the aorta, apparently formed by a hernial protrusion of the internal and middle through an opening in the ex-

ternal, the tumor being about the size of a walnut and having very thin and transparent coats. On close examination, this preparation appears to me to be of a very doubtful character; the external coat ceases abruptly by a ragged edge at the base of the tumor, and has all the appearance of having been dissected off.]

By the term *mixed* aneurism, Dr. A. Monro, senior, implied the state of a true aneurism, when its cyst had burst, and the blood was diffused in the adjacent cellular substance; an event which is frequent. Besides these varieties of aneurism, the *aneurismal varix*, or *venous aneurism*, and the *aneurism by anastomosis*, constitute diseases which are usually regarded as cases pertaining to the present subject, though incapable of being comprised under the ordinary definition of an aneurism.

An aneurism may then be defined to be a tumor filled with blood, either in a fluid or solid state, usually attended with pulsation, and the sac of which has an opening in it, by which it communicates with the artery, from which the blood is transmitted into it. Lisfranc defines it, “a tumor formed by arterial blood, and communicating with an artery,” and divides all aneurisms into *traumatic* and *spontaneous*, according as they happen to be produced by a wound, or disease of the coats of the artery. (*De l’Oblitération des Artères dans les Aneurismes*, p. 6.)

Nothing can be more manifest than the fact, that, previously to the discovery of the circulation of the blood, no correct nor valuable opinions could have prevailed respecting the diseases which now go under the name of aneurisms. Indeed, it was not until after the days of Aristotle, that any distinction was made between the swellings of veins and those of arteries; such vessels not having been at that early period distinguished from each other. Their differences were first pointed out by Rufus of Ephesus. Down to Galen, however, nothing like consistency was established in the notions respecting aneurism. His opinion was, that all tumors of this nature were produced either by anastomosis, or by rupture: and though he has described their symptoms, he has not informed us of the characters by which each of these cases was distinguishable, one from the other. Paulus Ægineta divides aneurism into two sorts, both of which, he says, are attended with extravasation, and of course with rupture. Vesalius, who first applied anatomy to the investigation of disease, described aneurism arising from the *rupture of a dilated aorta*; the first specimen, I believe, on record of this form of disease. (*Bonetus Sepulch. Anat. lib. iv. sect. 2.*)

The combination of rupture with dilatation of the artery, was afterwards more particularly noticed by Nuck (*Oper. Chir. &c. Lugd. 1692*); but it was Fernelius who first promulgated the doctrine, that aneurisms were always dilated arteries. (*Universa Medicina De Extern. Corp. Affect. lib. vii. cap. 3. Venet. 1564.*)

This opinion was espoused by Forrestus, Diemerbroek, and others; but at length, the inaccuracy of attempting to refer every aneurism solely to dilatation of the coats of the vessel, was established by the observations of Lancisi, Freind, Guattani and Morgagni. In short, as Mr. Hodgson has stated, these authors proved, that aneurism may be produced either by the rupture, or the dilatation

of the coats of an artery, or by a combination of both circumstances, the dilatation having preceded the rupture. (*On the Dis. of Arteries*, &c. 8vo. Lond. 1815.)

In truth, this admission of aneurism by dilatation, and of aneurism by rupture of the coats of an artery, together with the frequent combination of both circumstances, became the prevailing undisturbed doctrine of every surgical school, until Professor Scarpa, inclining to the tenets of Sylvaticus (*De Aneurysmate Tract.* Venetiis, 1600, 4to.), ventured to question the correctness of the common opinion about the dilatation of all the arterial coats. However, after the very clear and satisfactory elucidation of this disputed point by my friend Mr. Hodgson and others, as well as by several preparations in the Hunterian collection (see *Guthrie, On Dis. of Arteries*), the accurate views of the subject, first taken by Morgagni and the other eminent writers specified above, may be regarded as established beyond the possibility of dispute. At the same time, it is not to be supposed that Scarpa means to say, that the arteries are not subject to a morbid dilatation; on the contrary, he gives a particular description of this affection, which he carefully discriminates from aneurism.

Previously to offering a more particular account of the doctrine taught by Scarpa, respecting the formation of aneurism, as well as of the chief facts which may be adduced against a part of such doctrine, it seems proper to make the reader acquainted with the various forms of the disease, their ordinary symptoms, and a few pathological facts.

When an artery becomes dilated spontaneously (attended with particular circumstances marking its difference from another form of dilatation, which, as I shall explain, perhaps ought not to be set down as aneurismal), the swelling is commonly named a *true* or *genuine aneurism*. In such cases, the artery is either enlarged at only a small part of its track, and the tumor has a determinate border, or the vessel is dilated for a considerable length; in which circumstance the swelling is oblong, and loses itself so gradually in the surrounding parts, that its margin cannot be exactly ascertained. The first case, which is the most common, is termed the *circumscribed true aneurism*; the last, the *diffused true aneurism*; a case, however, which would be looked upon by Scarpa only as a specimen of dilatation, different in several particulars from aneurism, as will be hereafter noticed. When blood escapes from the wound or rupture of an artery into the adjoining cellular substance, the opening in the skin having closed, the swelling is denominated a *spurious* or *false aneurism*. In this instance, the blood either collects in one mass, distends the cellular substance, and condenses it into a cyst, so as to form a distinctly circumscribed tumor; or it is injected into all the adjacent cellular substance, and extends along the course of the great vessels, from one end of the limb to the other, thus producing an irregular oblong swelling. The first case is named a *circumscribed false aneurism*; the second, a *diffused false aneurism*. (*Richter's Anfangsgr.* b. i.)

When an aneurismal sac is formed upon a dilated artery, the walls of the vessel are sometimes thinner than usual; and some parts of them may become expanded into pouches, or even engrafted upon the original swelling, the prominent points being always the thinnest. This kind of

case is sometimes termed a *sacculated aneurism*, of which there is a good specimen in the Hunterian collection, remarkable also as exhibiting an aneurism opening by ulceration into the pulmonary artery. (See *Guthrie, On Dis. of Arteries*, p. 59.)

Aneurism by dilatation is distinguished by Breschet into four varieties, the names of which are determined by the differences in the shape of the expansion of the arterial tube. For instance, 1. *True sacciform aneurism*: 2. *True fusiform aneurism*: 3. *True cylindroid aneurism*, subdivided into that of the large arteries, and into that of the small arteries, or the *aneurism by anastomosis* of John Bell, and the *erectile tumors* of Dupuytren: 4. *True varix-like aneurism*, or *aneurisma cirsoideum*. In *sacciform aneurism*, the vessel has at one point of its circumference a small sac, consisting of an expansion of the arterial tunics. This variety is most frequent in the aorta, but sometimes on the carotid and iliac arteries, and even on those of the limbs. In this aneurism, all the arterial tunics are simultaneously dilated; but as the internal and middle ones have but a limited degree of extensibility, the sacciform aneurism does not generally exceed the size of a filbert, though Breschet has noticed some on the aorta as large as a hen's egg. (See *Breschet, Sur Différentes Espèces d'Aneurismes*, p. 12, &c.)

In the *true fusiform aneurism*, the dilatation extends over the whole circumference of the vessel: all the coats participate in it. The calibre of the artery, after becoming wider and wider gradually, for a certain portion of the track of the vessels, then lessens in a manner equally gradual, till it has resumed its natural diameter.

The *cylindroid aneurism* of Breschet might be regarded only as a variety of the fusiform, inasmuch as an abrupt transition from a given calibre to a much more capacious one is never observed. Yet, according to the investigations of Breschet, cases present themselves in which the artery is uniformly dilated through a track of one or two feet, the cylindrical form being here strictly preserved. This pathological fact has been noticed by Breschet in the arteries of the limbs, and in those of the brain, and of the splanchnic cavities. (*Op. cit.* p. 25.)

In the *true varix-like aneurism*, the artery is described by Breschet as being not only dilated, but tortuous, and occasionally studded with small sacciform tumors. The parietes of the vessel are thin and collapsed; while, in the other case, they are rather thickened. [This is the condition termed *cirroid*, in which the coats of the vessel are thinned, and the artery itself elongated and tortuous.] Such is Breschet's classification of true aneurism; a classification which, embracing, as it does, aneurism by anastomosis and erectile tumors, and these of different kinds, presents a good deal of novelty.

[Aneurisms may more conveniently be arranged into the *fusiform*, the *sacculated*, and the *dissecting*.

By the *fusiform* or *tubular aneurism* is meant that form of the disease in which all the coats of the artery are equally expanded throughout the whole circumference of the vessel. The artery is always elongated as well as dilated. These uniform dilatations are chiefly seated in the back of the aorta, and may attain a very great magnitude.

By the *sacculated aneurism* is meant a tumor that springs from the side of an artery, or of a

tubular aneurism, with the interior of which it communicates by a narrow aperture called the mouth of the sac. This form of aneurism is divided into the *true* and the *false* varieties. By the *true* is meant the case in which there is a partial dilatation of all the coats of the vessel. By the *false*, that is when there is a dilatation of one, or at most two, of the coats, with rupture of the rest. There are two varieties of the *false* aneurism — the *circumscribed* and the *diffused*. By the *circumscribed false aneurism* is meant that form of the disease in which the blood is still contained within a sac formed by at least one of the arterial coats, however expanded and altered in its structure this may be. In the *diffused false aneurism* the blood is extravasated into the cellular tissues of the limb or part, through which it may either be widely spread or be confined by the matting together of the parts around into a kind of sac.

The *dissecting* aneurism is that form of the disease in which the sac is contained in the walls of the artery between its coats. A rupture takes place through the internal coat into the middle one, which is split into two layers, often to a considerable extent. I have observed that dissecting aneurisms arrange themselves in three forms:—1. The blood, after passing through the laminae of the middle coat, becomes diffused outside the vessel. 2. The blood passing between the laminae of the middle coat is prevented bursting internally by the thickened outer coat, and bursts again through the internal coat into the interior of the vessel, thus forming a channel through the coat, both ends of which commence with the interior of the vessel. 3. The blood forms a permanent sac in the interior of the coats of the vessel, between the laminae of the middle coat. In the following pages, however, the definitions of aneurism as given by Mr. Cooper are preserved, in order that the author's meaning may not be departed from.]

The following are the symptoms of a true circumscribed aneurism:—The first thing which the patient perceives is an extraordinary throbbing in some particular situation, and on paying a little more attention he discovers there a small soft pulsating tumor, which in a great measure disappears when compressed, but returns again as soon as the pressure is removed. With the return of pulsation, and of the swelling, a peculiar thrilling feel is experienced, caused by the passage of the blood into the sac. [On the application of the stethoscope, a bellows murmur or a bruit of some kind, perhaps rasping or sawing, will be readily perceived, synchronous with the pulse in the artery.] If the artery be compressed on the distal side of the swelling, this will be rendered still larger and tenser. A spontaneous aneurism is generally slow in its growth, not perhaps exceeding the size of an egg in a year, and rarely that of a flattened orange. (*Guthrie*, op. cit. p. 108.) At first it is generally unattended with pain, or change in the colour of the skin. The pulsation is synchronous with the beat of the artery. It is eccentric and distensile. When once the tumor has originated, it continually grows larger, though very gradually, and at length attains a considerable size. In proportion as it becomes larger, its pulsations often become weaker; and, indeed, when the disease has acquired much magnitude, they are frequently either quite lost, or only distinguishable with the stethoscope. [It does not necessarily follow that the pulsation lessens in force as the aneurism grows

larger, on the contrary, the reverse is often observed. It is only when the aneurism has become solid as well as large that the pulsations are less distinct.] The diminution of the pulsation has been partly ascribed to the coats of the artery losing their dilatable and elastic quality, in proportion as they are distended, but chiefly to the lamellated coagulated blood deposited on the inner surface of the sac, particularly in large aneurisms, in which the motion of some of the blood is always interrupted. Immediately such coagulated blood lodges in the sac, pressure can only produce a partial disappearance of the swelling. This deposition of lamellated coagulum in the aneurismal sac is a circumstance of considerable importance; for it has been well explained by Mr. Hodgson, that it is the mode by which the spontaneous cure of the disease is in most instances effected. "One of the circumstances which, in the most early stage, generally attend the formation of aneurism (says this author), is the establishment of that process which is the basis of its future cure. The blood, which enters the sac soon after its formation, generally leaves upon its internal surface a stratum of coagulum, and successive depositions of the fibrous part of the blood gradually diminish the cavity of the tumor. At length, the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery, which supplies the disease, forming a firm plug of coagulum, which extends on both sides of the sac, to the next important ramifications that are given off from the artery. The circulation through the vessel is thus prevented, the blood is conveyed by collateral channels, and another process is instituted, whereby the bulk of the tumor is removed," &c. (*On the Diseases of Arteries*, &c. p. 114.) Whether there is any truth in Kreysig's conjecture, that some of the lymph may exude from the inside of the sac itself, I cannot presume to say; he owns, however, that the inner concentric layers presenting the appearance of being deposited last, is a circumstance rather against his surmise, though he adverts to some other circumstances which incline him to look upon the opinion as possibly correct. (*German Translation of Mr. Hodgson's Work*, p. 124.)

When the aneurism has not been caused by dilatation, but by a rupture of the inner coats of the vessel, the patient usually refers to some particular period, and generally to one of exertion, when this rupture was indicated by pain of a more or less acute nature, which either continued with a corresponding degree of lameness, or left such a sense of uneasiness as made the patient put his hand frequently on the part. On one of these occasions, the pulsating tumor is discovered. If the aneurism, whether of one kind or another, be in the ham, the patient first limps; then the leg becomes permanently bent; and when the tumor begins to press on the nerves, veins, and absorbents, the toes and leg are extremely painful, and the foot and leg œdematous. (See *Guthrie*, *On Dis. of Arteries*, p. 109.)

It is the general belief, that the pulsation of the tumor is produced by the jet of blood into it at each stroke of the heart. This opinion, however, is disputed by an eminent writer, who asks, Is it true, that the pulsation of aneurisms proceeds from the entrance of a more considerable stream of blood into the sac, and the distention of the swelling thereby produced? In aneurisms, which

have only a narrow communication with the arterial tube, or which are filled with laminated coagula, the idea, says he, is quite inadmissible: the aneurism is rather shaken, as it were, like other different swellings in the vicinity of an artery, by the stroke of the heart occasioning a stretching of the whole arterial system, and at the same time communicating an impulse to the column of blood. (*Kreysig, Germ. Tr. of Mr. Hodgson's Work*, p. 143.) Here I am by no means disposed to coincide with this distinguished physician, whose sentiments appear to me to be refuted by the fact, that whenever any change happens calculated to lessen, or entirely stop the influx of blood into the sac, the pulsation either diminishes, or ceases in proportion. Thus, when Kreysig adverted to the pulsation of aneurisms, in which much coagulated blood was deposited, he might at the same time have mentioned the effect which such deposition has in weakening the pulsation, the layers of coagulated blood, within the tumor, being in the natural mode of cure, "the means by which the force of the circulation is removed from the sac, and the fatal termination of the disease by rupture is prevented." (See *Hodgson, On Diseases of the Art. and Veins*, p. 126.) In proportion as the aneurismal sac grows larger, the passage of blood into the artery beyond the tumor is lessened. Hence, in this state, the pulse, below the swelling, becomes weak and small, and the limb frequently cold and œdematous. On dissection, the lower continuation of the artery is found preternaturally small and contracted. The pressure of the tumor on the adjacent parts may also produce a variety of symptoms, — ulceration, absorption of bone, &c. Sometimes (says Richter) an accidental contusion, or concussion, may detach a piece of coagulum from the inner surface of the cyst, and the circulation through the sac be obstructed by it: nay, he asserts, that the coagulum may possibly be impelled quite into the artery below, so as to induce important changes. The danger of an aneurism arrives when it is on the point of bursting, by which occurrence the patient usually bleeds to death, and this sometimes in a few seconds. In an external aneurism, the fatal event may generally be foreseen, as the part about to give way becomes particularly tense, elevated, thin, soft, and of a dark purple colour. (See *Richter's Anfangsgr.* band. i.)

External aneurisms do not burst by ulceration, but by the formation and detachment of a slough. I believe this is a fact which was first particularly pointed out in the early editions of my work; and it gives me pleasure to find, that it is a statement which entirely coincides with that subsequently made by several writers of eminence, especially Mr. A. Burns (*On Diseases of the Heart*, p. 225), and Boyer (*Traité des Maladies Chirurgicales*, t. ii. p. 98).

As far as my information extends, Mr. A. Burns first explained the very different mode of rupture which happens in internal aneurisms: these, he observed, generally burst by actual laceration, and not by sphacelation of the cyst. (*On Diseases of the Heart*, p. 225.) But a still more particular account of the process by which external and internal aneurisms burst is delivered by Mr. Hodgson. When the sac points externally (says this gentleman), it rarely or never bursts by laceration, but the extreme distention

causes the integuments and investing parts to slough; and upon the separation of the eschar, the blood issues from the tumor. A similar process takes place, when the disease extends into a cavity which is lined by a mucous membrane, as the œsophagus, intestines, bladder, &c. In such cases, the cavity of the aneurism is generally exposed by the separation of a slough, which has formed upon its most distended part, and not by laceration. But when the sac projects into a cavity lined by a serous membrane, as the pleura, the peritoneum, the pericardium, &c., sloughing of these membranes does not take place; but the parietes of the tumor having become extremely thin in consequence of distention, at length burst by a crack, or fissure, through which the blood is discharged. (*On the Diseases of Arteries, &c.* p. 85.) An aneurism, however, which burst into the œsophagus, and which I had an opportunity of examining after the patient's death, was found to have done so by an ulcerative process. The mucous membrane of the trachea is also sometimes perforated by ulceration, the commencement of which is delineated in Cruveilhier's plates. (See *Anat. Pathol.* livr. iii. pl. 3 et 4.)

When the aneurism is of considerable size, the collateral arteries, which originate above the swelling, are manifestly enlarged. This enlargement of the collateral arteries above the disease ensures to the limb below the tumor an adequate supply of blood, when the obstruction to its passage through the diseased artery becomes considerable, or when this vessel has been rendered totally impervious by a surgical operation performed for the cure of the complaint.

In the advanced stage of an aneurism, the skin is found extremely thin, and confounded, as it were, with the aneurismal sac. The cavities of the cellular substance near the disease are either filled with serum, or totally obliterated by adhesion. The adjacent muscles, whether they lie over the aneurism, or to one side of it, are stretched, displaced, dwindled, and sometimes confounded with other parts. It is the same with the large nervous cords situated at the circumference of the tumor: they are pushed out of their natural situation, diminished in size, sometimes adherent to the outside of the sac, and so changed as scarcely to admit of being known again. Lastly, the cartilages and the bones themselves are not exempt from the mischief which the aneurismal swelling produces in all the surrounding parts: they are gradually destroyed, and, at length, not the least trace of their substance remains, just in the same way as the bones of the cranium are destroyed by fungous tumors of the dura mater. (See *DURA MATER*.) Even the cartilages of the larynx, and rings of the trachea, are sometimes destroyed; this tube is pierced, and the blood escapes into it, or the aneurism bursts into the œsophagus. (*Boyer, Traité des Maladies Chir.* t. ii. p. 99; *S. Cooper, Med. Chir. Trans.* vol. xvi. p. 399, &c.) As I shall hereafter explain, however, the pressure of an aneurismal tumor more quickly produces an absorption of bone than of cartilage. Aneurism of the arch of the aorta, or of the subclavian artery (*Guthrie, On Diseases of Arteries*, p. 63), sometimes occasions a dislocation of the sternal end of the clavicle.

While an aneurism is small and recent, it does

not generally cause much pain, nor seriously impede the functions of the limb. But when it has increased, several complications are produced. Thus, the dragging of the long saphenous nerve, by femoral aneurisms, frequently occasions acute pain in the course of this nerve as far as the great toe. The distention of the sciatic nerve by the popliteal aneurism, sometimes brings on intolerable pain, which extends to all the parts to which the nerve is distributed, and which can hardly ever be appeased by the topical use of opiate applications. Pain is often one of the earliest symptoms of aneurisms; it is of two kinds, either lancinating, darting, and radiating along the course of the nerves that are compressed by the tumor, or else of a boring, wearing, gnawing, character, from the compression and erosion of the neighbouring parts by the increase of the sac. The first pain is usually intermittent, the second variety is permanent. The compression of the veins and lymphatics give rise to œdema, numbness, and coldness of the limb. And, finally, the long-continued pressure of the aneurism on the neighbouring bones causes their destruction. (*Boyer, t. ii. p. 105.*)

In true or spontaneous aneurism, the coats of the artery are not always in the same state, the kind of changes observed depending upon the progress of the tumor. In the early stage of the disease, either the whole cylinder of the vessel, or only a part of its circumference, is dilated; but this period is generally of short duration, especially in arteries of middling size, because their middle coat is capable of less resistance than that of the larger arteries like the aorta, where this coat is yellowish, firm, and very elastic. As Breschet remarks, this difference of resistance in the middle coat of the aorta, and the branches given off from it, accounts for the rarity of true aneurisms either in the small arteries, or those of middling size, and their greater frequency in the principal trunk of the arterial system.

At length, in consequence of the increasing distention, some of the coats of the artery possessing the least elasticity give way; and these are found to be the internal and middle coats; while the external one still makes resistance, and continues to be more and more dilated by the lateral impulse of the blood.

The second stage of true or spontaneous aneurism is that in which the surgeon is usually consulted; that in which the tumor increases more rapidly, and therefore begins to excite greater attention. The disease has now made its way through the internal and middle coats of the artery, and the external coat yields with more facility. In this stage, if the artery be only covered by a serous membrane, which soon gives way, the patient's life is endangered, and death often brought on by the rupture of the tumor. Examinations of the dead subject under these circumstances, have frequently led to mistaken notions; and, doubtless, if various swellings of this kind had not been found in different degrees, or stages, in the same individual, one might have been disposed to join Scarpa in the belief, that no aneurism consists of a dilatation of all the arterial coats. (*Breschet, Fr. Transl. of Mr. Hodgson's Work, p. 128, 129.*)

The change of an aneurism from the circumscribed into the diffused state is indicated by a sudden reduction, or stoppage of the pulsations of the tumor, often preceded by a sensation of some-

thing breaking, or giving way in the limb, which becomes all at once very painful. The temperature of the foot suddenly falls, and the swelling undergoes a rapid increase, and also becomes more diffused. The two latter circumstances may indeed not be very obvious, when the limb is already very œdematous, or the aneurismal sac has given way in a deep situation, and the blood has escaped into the cellular tissue between the muscles and under the fascia. In these cases, however, there is always some point of the leg or foot marked by a livid discoloration; and as the distention of the cellular tissue with blood, and the augmented interruption of the circulation in the limb, bring on a tendency to gangrene, the patient's pulse becomes accelerated. Here the danger of mortification is much greater than when the sac bursts, and the blood, instead of passing extensively into the cellular tissue, accumulates in one mass. Mr. Lawrence communicated to the Med. Chir. Society an instance in which the mass of blood collected in the thigh was so enormous after the giving way of a femoral aneurism under the skin, that, when the coagula were removed, by means of a free incision, some time after the artery had been tied, the finger could be passed nearly all round the thigh-bone. But, notwithstanding this mass of blood, and profuse suppuration, the patient recovered. The sudden extravasation of so large a quantity of blood into the substance of a limb by an aneurism becoming diffused, may occasion fatal syncope. (*See Med. Chir. Trans. vol. xvi. p. 321.*)

When the sac of an aneurism has burst in the foregoing manner, the propulsion of blood into it from the heart can evidently no longer have the effect of producing a full and sudden distention of it, as more or less of that fluid will either escape from it into the cellular membrane, or collect in one mass out of the aneurismal cavity. In general, however, the pulsations are only weakened at first and several days elapse before they entirely cease. Another cause that has a powerful effect in putting an end to the pulsations, is an increase in the quantity of coagulated blood and fibrine in the sac; the inevitable result of the stream of blood through it becoming more and more retarded in proportion as the obstruction of the circulation in the leg augments. In cases of doubt whether the reduction and stoppage of the pulsation are owing to the circumstances here adverted to, or to the sac having become filled with lamellated blood, without any rupture of it and change of the aneurism from the circumscribed to the diffused state (a condition promising the accomplishment of a complete cure), the stethoscope should be employed, whereby, in the former case, the sound of the jet of blood into the sac, the bellows-sound, as it is termed, will be perceived. This symptom, with others to which I have adverted, would render the state of things sufficiently clear. (*See Med. Chir. Trans. vol. xvi. p. 320, &c.*)

A *false aneurism* is always attended with at least a rupture, or giving way of the inner coat of the vessel, and usually with a breach in both this and the muscular coat, the outer elastic tunic forming the pouch in which the blood collects. But, after the swelling has attained a certain size, this coat also bursts, and then the blood either becomes diffused, or a large circumscribed space is formed for it by the condensation of the surrounding cellular membrane. False

aneurisms, when produced by a wound or puncture, are of course from the first attended with a division of all the coats of the vessel. This form of the disease is often seen at the bend of the arm, where the artery is exposed to injury in venesection. (See HEMORRHAGE.) In this circumstance, as soon as the puncture is made, the blood gushes out with unusual force, and in a bright scarlet, irregular, interrupted current; flowing out, however, in an even, and less rapid stream, when pressure is applied higher up than the wound. These last are the most decisive marks of the artery being opened; for blood may issue from a vein with great rapidity, and in a broken current, when the vessel is turgid, and situated immediately over the artery, which imparts its motion to it. The surgeon endeavours precipitately to stop the hemorrhage by pressure, and in general a *diffused false aneurism* is the result. The external wound in the skin is closed, so that the blood cannot escape; but this does not hinder it from passing into the cellular substance. The swelling, thus produced, is uneven, often knotty, and extends upward and downward along the track of the vessel. The pulsation is more feeble than that of a true aneurism, and is sooner lost. The skin is also usually of a dark purple colour. The swelling increases, as long as the internal hemorrhage continues; and if this should proceed beyond certain bounds, mortification of the limb ensues. Such is the *diffused false aneurism* from a wound; a case which Lisfranc regards only as an extravasation of arterial blood, and reluctantly classes with aneurism at all. (*De l'Oblitération des Artères dans le Traitement des Aneurismes*, p. 6.)

The *circumscribed false aneurism*, from a wound or puncture, arises in the following manner. When proper pressure has been made in the first instance, so as to suppress the hemorrhage, but the bandage has afterwards been removed too soon, or before the artery has healed, the blood passes through the unclosed wound, or that which it has burst open again, into the cellular substance. As this has now become agglutinated by the preceding pressure, the blood cannot diffuse itself into its cells, and, consequently, a mass of it collects in the vicinity of the aperture of the artery, and distends the cellular substance in the form of a sac. Sometimes, though not often, the circumscribed false aneurism originates immediately after the opening is made in the artery. This chiefly happens when the aperture in the vessel is exceedingly small, and, consequently, when the hemorrhage takes place so slowly that the blood, which is first effused, coagulates, and prevents the entrance of that which follows into the cavities of the cellular substance, and, of course, its diffusion. A traumatic false aneurism differs materially from one which has taken place spontaneously, or as a consequence of disease; for, in the latter, the artery is generally unsound for some distance above and below the tumor. In the aneurism from a wound, the artery is perfectly sound, except inasmuch as the injury is concerned, and no effort is yet made by nature to obliterate the artery below or beyond the aneurism, which frequently takes place, when an aneurism occurs from disease. There are also other important differences in relation to the collateral circulation, and the requisite surgical operation. (See Guthrie, *On the Diseases of Arteries*, p. 82.)

In aneurism, the separation of the external from the middle coat of an artery is generally effected with difficulty; the external coat becomes stretched and distended, and an aneurismal tumor is formed. To this, however, there are a few uncommon exceptions; for the blood may be forced along the artery, separating the external and middle coats from each other, and forming a pouch several inches in length, which may or may not completely surround the vessel. In one case, reported by Mr. Guthrie, it formed a pouch on the anterior part of the descending aorta, about six inches in length, extending to the sides, and in one place nearly surrounding it. A horizontal fissure, about half an inch in extent, near the upper part of the swelling, allowed the blood to pass through the inner and middle coats, and to effect this separation, *which*, as Mr. Guthrie observes, *could only have arisen from disease previously existing in the part.* (See Guthrie, *On Dis. of Arteries*, p. 40.) Laennec gave an account of a very similar, but of a more extensive case of this kind, in a person who was not suspected during life to have disease of the heart or arteries. (*De l'Auscult.* t. ii. p. 700.) Mr. Guthrie also met with a third example, which is the preparation No. 368 A. in the Museum of the College of Surgeons. Just below the point where the innominate is given off, the inner and middle coats are ruptured along half the circle of the aorta, as cleanly as if cut with a knife. The effused blood has separated the outer from the fibrous coat down to the origin of the aorta. The separation is also continued along the descending aorta for an inch beyond the left subclavian, and the interval filled with blood. The arteria innominate had in the front half of it another transverse rent in all its coats, where the hemorrhage took place which killed the patient. The descending portion of the aorta, and the roots of the great vessels, are covered with atheromatous patches, and in part with bony scales. The coats were all easily separable, and softer and more readily broken than natural. (Guthrie, *op. cit.* p. 43.)

Cases of the foregoing description are sometimes termed *dissecting aneurisms* (*vide ante*, p. 142), of which the late Mr. Shekelton described one modification, not previously noticed by any other pathologist, and the peculiarity of which was, that after the blood had forced its way through the inner and middle coats of the vessel, it not only detached the middle from the outer coat to the extent of four inches, but then forced its way into the canal of the artery again, through the middle and inner coats: thus two channels existed for the passage of the blood. In the end, the formation of the new passage led to the obliteration of the original one, or corresponding portion of the arterial tube. (See *Dublin Hospital Reports*, vol. iii.)

FORMATION OF ANEURISMS.

If the doctrines of Scarpa, published in 1804, had proved correct, the grand distinction of aneurism into *true* and *false* must have been rejected as erroneous: "for," says he, "after a very considerable number of investigations, instituted on the bodies of those who have died of internal or external aneurisms, I have ascertained, in the most certain and unequivocal manner, that there is only one kind or form of this disease, viz. that

caused by a solution of continuity, or rupture of the proper coats of the artery, with effusion of blood into the surrounding cellular substance; which solution of continuity is occasioned sometimes by a wound, a steatomatous, earthy degeneration, a corroding ulcer, or a rupture of the proper coats of the artery, I mean the internal and muscular, without the concurrence of a preternatural dilatation of these coats being essential to the formation of this disease; and, therefore, that every aneurism, whether it be internal or external, circumscribed or diffused, is always formed by effusion." (*On Aneurism*; transl. by Wishart, Pref.)

According to Scarpa, it is an error to suppose that the aneurism at the curvature or in the trunk of the aorta, produced by a violent and sudden exertion of the whole body, or of the heart in particular, and preceded by a congenital relaxation of a certain portion of this artery, or a morbid weakness of its coats, ought always to be considered as a tumor formed by the distention or dilatation of the proper coats of the artery itself, that is, of its internal and fibrous coats. Scarpa considers it quite demonstrable, that such aneurisms are produced by a corrosion and rupture of these tunics, and, consequently, by the effusion of arterial blood under the cellular sheath, or other membrane, covering the vessel. If ever there be a certain degree of preceding dilatation, it is not essential to constitute the disease, for it is not a constant occurrence; most aneurisms are unpreceded by it, and, in those rare cases in which an aneurism is preceded and accompanied by a certain degree of dilatation of the whole diameter of the curvature of the aorta, there is an evident difference between an artery simply enlarged in diameter, and the pouch which forms an aneurismal sac.

Careful dissections, says Scarpa, will prove that the aorta contributes nothing to the formation of the aneurismal sac, and that this is merely the cellular membrane, which, in the sound state, covered the artery, or that soft cellular sheath which the artery received in common with the neighbouring parts. This is raised by the blood into the form of a tumor, and is covered, in common with the artery, by a smooth membrane.

This eminent professor does not deny that, from congenital relaxation, the proper coats of the aorta may occasionally yield and become disposed to rupture; but he will not admit that dilatation of this artery precedes and accompanies all its aneurisms, or that its proper coats ever yield so much to distention as to form the aneurismal sac. *The root of an aneurism of the aorta never includes the whole circumference of the artery*; but the aneurismal sac arises from one side of it in the form of an appendix, or tuberosity. On the contrary, *the dilatation of the artery always extends to its whole circumference*, and, therefore, differs essentially from aneurism. Thus he urges, that there is a remarkable difference between a dilated and an aneurismal artery, although *these two affections are sometimes found combined together*, especially at the origin of the aorta. If we also consider that the dilatation of an artery may exist without any organic affection, the blood being always in the cavity of the vessel; that, in an artery so affected, there is never collected any grumous blood, or polypous layers; that the dilatation never forms a tumor of considerable bulk; and that, while

the continuity of the proper coats remains uninterrupted, the circulation of the blood is not at all, or not so sensibly changed, we shall be obliged to allow, that aneurism differs essentially from one kind of dilatation of an artery.

Some additional remarks on this topic, more recently published by Scarpa, will be presently considered.

By dissections of arteries, both in the sound and morbid state, Scarpa endeavours to demonstrate what share the proper and constituent coats of the artery have in the formation of the aneurismal sac, and what belongs to the cellular covering, and other adventitious membranes surrounding the artery.

The covering of an artery is merely an adventitious sheath, which the vessel receives in common with the parts in the vicinity of which it runs. On cutting an artery across in its natural situation, the segment of the cut vessel retires and conceals itself in this sheath.

This cellular covering is most evident round the curvature and trunk of the aorta, the carotid, mesenteric, and renal arteries; it is less dense round the trunks of the brachial, femoral, and popliteal arteries. The pleura lies over the cellular sheath of the arch of the aorta, and over that of the thoracic aorta; while that of the abdominal aorta is covered by the peritoneum. Both these smooth membranes adhere to, and surround, two thirds of the circumference of the vessel. The great arteries of the extremities are not covered, in addition to the cellular substance, by any smooth membrane of this sort, but by a cellular sheath, which is demonstrably distinct from the adipous membrane, and serves to enclose the vessels, and connect them with the contiguous parts.

When air, or any other fluid, is injected by a small hole, made artificially between the cellular covering and the subjacent muscular coat of the artery, the injected matter elevates into a tumor the cellular membrane, which closely embraces the artery, without properly destroying its cells, which it distends in a remarkable manner. When melted wax is injected, and pushed with much force, the cellular sheath of the artery is not only raised over the vessel, like a tumor, but the internal cells of that covering are also lacerated; and, on examining afterwards the capsule of the artificial tumor, it appears as if it were formed of several layers, rough and irregular internally, smooth and polished externally. The same thing happens when any injection is pushed with such force into an artery as to rupture the internal and muscular coats at some point of their circumference. Nicholls performed this experiment several times before the Royal Society. (*Philos. Trans.* an. 1728.) As soon as the internal coat is ruptured, the muscular one also gives way; but the external cellular sheath, being of an interlaced texture, and the thin laminae of which it is composed being not simply applied to one another, but reciprocally intermixed, is capable of supporting great distention, by yielding gradually to the impulse of the blood, without being torn or ruptured.

Scarpa is farther of opinion, that the same phenomena may be observed, when the internal coat of the aorta becomes so diseased as to be ruptured by the repeated jets of blood from the heart. In this circumstance, the blood, impelled by the

heart, begins immediately to ooze through the connections of the fibres of the muscular coat, and gradually to be infused into the interstices of the cellular covering, forming, for a certain extent, a kind of *ecchymosis*, or *extravasation of blood*, slightly elevated upon the artery. Afterwards, the points of contact between the edges of the fibres of the muscular coat, being insensibly separated, the arterial blood, penetrating between them, fills the cellular covering of the artery, and raises it after the manner of an incipient tumor. Thus, the fibres and layers of the muscular coat, being wasted, or lacerated, or simply separated from each other, the arterial blood is carried with great force, and in greater quantity than before, into the cellular sheath of the artery, which it forces more outwards; and, finally, the divisions between the interstices of the cellular coat, being ruptured, it is converted into a sac, which is filled with polypous concretions and fluid blood, and at last forms, strictly speaking, the aneurismal sac. The internal texture, although apparently composed of membranes placed one over the other, is, in fact, very different from that of the proper coats of the artery, notwithstanding the injured vessel and aneurismal sac are both covered externally in the thorax and abdomen with a smooth membrane.

Scarpa has examined a considerable number of aneurisms of the arch, and of the thoracic and abdominal trunks of the aorta, without finding a single one in which the rupture of the proper coats of the artery was not evident, and in which, consequently, the sac was produced by a substance completely different from the internal and muscular coats.

The aneurismal sac never comprehends the whole circumference of the vessel. At the place where the tumor joins the side of the tube, the aneurismal sac presents a kind of constriction, beyond which it becomes more or less expanded. This would never happen, or rather the contrary circumstance would occur, if the sac were formed by an equable distention of the tube and proper coats of the affected artery. In incipient aneurisms, at least, the greatest size of the tumor would then be in the artery itself, or root of the swelling, while its fundus would be the least. But, *whether aneurisms be recent and small, or of long standing and large, the passage from the artery is always narrow, and the fundus of the swelling greater in proportion to its distance from the vessel.* The sac is always covered by the same soft dilatable cellular substance which united the artery in a sound state to the circumjacent parts. Such cellular substance, in aneurisms of the thoracic aorta, is covered by the pleura, and, in those of the abdominal aorta, by the peritoneum, which membranes include the sac and ruptured artery, presenting outwardly a continued smooth surface, just as if the artery itself were dilated. But, if the aorta be opened lengthwise on the side opposite the constriction, or neck of the tumor, the place of the ulceration, or rupture, of the proper coats of the artery, immediately appears within the vessel, on the side opposite to that of the incision. The edge of the fissure, which has taken place, is sometimes fringed, often callous and hard, and through it the blood formed for itself a passage into the cellular sheath, which is converted into the aneurismal sac. If, as sometimes

happens, in the arch of the aorta near the heart, the artery, before being ruptured, has been somewhat dilated, it seems, at first, as if there were two aneurisms; but the constriction, which the sac next to the artery presents externally, points out exactly the limits, beyond which the internal and muscular coats of the aorta had not been able to resist the distention, and where of course they have been ruptured. The partition, which may always be seen dividing the tube of the artery from the aneurismal sac, and which is lacerated in its middle, consists of nothing else than the remains of the internal and muscular coats of the ruptured artery.

By carefully dissecting the proper coats of the ruptured aorta in its situation, and comparing them with the cellular substance forming the sac, Scarpa affirms, that the truth of the preceding statement may be indisputably demonstrated.

When an incision is made lengthwise in the side of the vessel opposite the rupture, its proper coats are found either perfectly sound, or a little weakened and studded with earthy points, but still capable of being separated into distinct layers. On the contrary, in the opposite side of the aorta, where the rupture is, the proper coats are unusually thin, and are only separable from each other with difficulty, or even not at all; they are frequently brittle like an egg-shell, and are disorganised and torn at the place where they form the partition between the ruptured artery and the mouth of the aneurismal sac. Continuing to separate these coats from within outwards, we arrive at the cellular sheath surrounding the aorta. This sheath being much thickened in large aneurisms, and adherent to the subjacent muscular coat of the artery at the place of the constriction of the sac, is likely to be mistaken for a dilated portion of the vessel itself. But, even in such cases, we may at last separate it, without laceration, from the tube of the artery, above and below the injury, and, successively, from the muscular coat, as far as the neck of the aneurism. Then, it is clear, the muscular coat does not pass beyond the partition, separating the cavity of the artery from that of the aneurismal sac, over which it is not prolonged, but terminates at the edge of the rupture like a fringe, or in obtuse points. Errors seem to Scarpa more apt to occur, in consequence of the aorta and sac being both covered by the pleura or peritoneum.

The portion of the aorta within the pericardium being only covered by a thin reflected layer of this membrane, such layer may also be lacerated, when the proper coats give way, and blood be effused into the cavity of the pericardium. Examples of this kind are related by Walter, Morgagni, and Scarpa himself. In the latter instance, on making an incision into the concave part of the aorta, opposite the tumor which had formed under the layer of the pericardium, which had also burst, by a small aperture, its internal coat, corresponding to the base of the swelling, was quite rough, interspersed with yellow hard spots, and actually ulcerated for the space of an inch in circumference. The preparation is preserved in the Museum at Pavia.

But, all other parts of the aorta having, between them and the pleura and peritoneum, a cellular sheath of a stronger and more yielding nature, which allows itself to be distended into a sac, and being strengthened, internally, by poly-

pous layers, and externally by the pleura or peritoneum, oppose for a long while the fatal effusion of blood.

Scarpa believes, that what he calls the chronic steatomatous, squamous degeneration of the artery, is more frequently the cause of its bursting than violent exertions of the whole body, blows, or an increased impulse of the heart. This kind of diseased change is very common in the curvature, and in the thoracic and abdominal trunks of the aorta. In the incipient state of such disease, the internal coat of the artery, loses for a certain space, its beautiful smoothness, and becomes irregular and wrinkled. It afterwards appears interspersed with yellow spots, which are converted into grains, or earthy scales, or into steatomatous and cheese-like concretions, which render the internal coat of the artery brittle, and so slightly united to the adjoining muscular coat, that, upon being merely scratched with the knife, or point of the nail, pieces are readily detached from it, and, on being cut, it gives a crackling sound, similar to the breaking of an egg-shell. This ossification cannot be said to be proper to old age, since it is sometimes met with in subjects not much advanced in life. The whole of the side of the artery, in that portion which is occupied by the morbid affection, is, for the most part, hard and rigid, sometimes soft and fungous; and, in most cases, the canal of the artery is preternaturally constricted. In the highest degree of this morbid disorganisation, true ulcerations are found on the inside of the artery, with hard and fringed edges, fissures, and lacerations of the internal and fibrous coats of the artery.

Having presented the reader with an abridged account of the most important remarks made by Scarpa in support of the doctrine he defends, I now annex his conclusions. 1. That aneurism is invariably formed by the rupture of the proper coats of the artery. 2. That the aneurismal sac is never formed by a dilatation of the proper coats of the artery, but, undoubtedly, by the cellular sheath, which the artery receives in common with the parts contiguous to it; over which cellular sheath the pleura is placed in the thorax, and the peritoneum in the abdomen. 3. That if the aorta, immediately above the heart, appears sometimes increased beyond its natural diameter, this is not common to all the rest of the artery: and when the aorta, in the vicinity of the heart, yields to a dilatation greater than natural, this dilatation does not constitute, properly speaking, the essence of the aneurism. 4. That there are none of those marks regarded by medical men as characteristic of aneurism from *dilatation*, which may not be met with in aneurism from *rupture*, including even the circumscribed figure of the tumor. 5. That the distinction of aneurism into *true* and *spurious*, adopted in the schools, is only the production of a false theory; since observation shows, that there is only one form of the disease, or that caused by a rupture of the proper coats of the artery, and an effusion of arterial blood into the cellular sheath, which surrounds the ruptured artery.

Such were the inferences made by Scarpa, in 1804, one of the most distinguished anatomists and surgeons of his time. Great as his authority was, several eminent modern surgeons, as Richerand, Boyer, Dubois, Dupuytren, Sabatier, Breschet, &c. did not yield to it, but still contended that, in some aneurisms, the coats of the artery were

dilated. These professors in France coincided with what has been usually taught upon this subject in the surgical schools of Great Britain. Every lecturer here has been accustomed to describe the distinctions of aneurisms into true and false, or into some cases which are accompanied with dilatation, and into others which are attended with rupture of the arterial coats. Many years ago, Mr. Hodgson, of Birmingham, published a valuable treatise, in which he differs from Scarpa, and joins those surgical writers who believe in the occasional dilatation of the coats of the arteries in this disease. He inquires, "Is every aneurism produced by a destruction of the internal and middle coats of the vessel? and does not a partial dilatation of these coats occasionally precede, and give rise to, their destruction? I believe that this is frequently the case. We have seen, that the disorganisation of the coats of an artery, by destroying their natural elasticity, will give rise to permanent dilatation of the whole circumference of the vessel; and there is every reason to expect, that a loss of its elasticity in a portion only of the diameter of the vessel, will give rise to a partial dilatation of its coats. Indeed, the proofs of a partial dilatation of the coats of an artery, particularly of the aorta, are incontestably established by the possibility of tracing the coats of the vessel throughout the whole extent of the expansion, and by the existence of those morbid appearances in the sac which are peculiar to the coats of the arteries.

"In the year 1811 (says Mr. Hodgson), I dissected an aneurism of the aorta, which was removed from the body of a young woman, by my friend, Dr. Farre. The sac was as large as a small melon, and had proved fatal by bursting into the posterior mediastinum, and subsequently into the cavity of the thorax. This aorta exhibited the formation of aneurism by partial dilatation in three distinct stages. The internal coat was throughout inflamed, and presented a fleshy and irregular appearance. At the arch of the aorta, there was a dilatation not larger than the half of a small pea. About two inches lower in the same vessel was a second dilatation, which would have contained hazel nut; and immediately above the diaphragm was the large aneurism which had proved fatal. I removed that portion of the vessel which contained the smallest dilatation, and macerated it until its coats could be separated without violence. I found that the dilatation existed equally in the three coats of the vessel, and, when separated each presented the appearance of a minute aneurism. The second dilatation exhibited the same circumstances in a more advanced stage. The coats of the vessels were more intimately adherent to each other than in a natural state, but, it was evident that the dilatation consisted in a dilatation of the internal, the middle, and the external coats of the aorta. In the large aneurism, the disorganised internal and middle coats could be traced for some distance into the sac, when the parts contained in the posterior mediastinum, and the vertebræ, formed the remainder of the cyst. There can be little doubt that this sac commenced in a dilatation of the coats of the vessel, similar to those appearances which existed in the superior portion of the dissection, and the artery appeared to illustrate the formation of aneurism by partial dilatation in three distinct stages." (Hodgson,

On the Diseases of Arteries and Veins, p. 66, 68. See also *G. Andral, Précis d'Anat. Pathol.* t. ii. p. 361.) So far as Kreysig's information extends, nobody before Mr. Hodgson had examined the structure of an aneurismal sac in this accurate manner, viz. by maceration, and the results, he thinks, are not liable to the slightest objections. (See the *German Transl. of Mr. Hodgson's Work, with Notes by Kreysig and Koberwein*, p. 109. Hanover, 1817.)

Mr. Hodgson has seen this partial dilatation in almost all the arteries which are subject to aneurism, at the divisions of the carotids and iliacs, in the arteries of the brain, &c.; and he agrees with Dr. Baillie (*Morbid Anatomy, &c.*), Laennec (*Cerattius, Beschreib. d. Krankh. Preparete d. Anat. Theatres zu Leipz.* p. 408, 8vo. 1819), and others, that aneurisms, at the origin of the aorta, are generally formed by dilatation of the coats of the vessel.

"Partial as well as general dilatation (says Mr. Hodgson) frequently precedes the formation of aneurism in the arteries of the extremities. A gentleman had a large aneurism in the thigh, which had undergone a spontaneous cure. Upon examining the limb after death, the popliteal artery was found to be thickened and covered with calcareous matter. A small pouch, which would have contained the seed of an orange, originated from the side of this artery. This little sac was evidently formed by a dilatation of the coats of the vessel. A man died from the sloughing of an aneurism in the ham; in the femoral artery there was a small aneurism, about as large as a walnut. The external coat was dissected from the surface of the tumor to a considerable extent. The internal and middle coats were evidently dilated, and contributed to the formation of the sac. The dilatation of these coats was gradual, and they continued for a considerable distance to form the sac, when they were inseparably blended with the surrounding parts." (Op. cit. p. 70.) In one particularly interesting case of popliteal aneurism recorded by Breschet, where the internal coat, and in part also the fibrous, could be traced over the swelling, there was likewise an aortic aneurism, extending from the heart to four inches above the bifurcation of the aorta, where the swelling ended in an abrupt and circular manner. The middle and external tunics were perfectly healthy; and the internal, with the cellular tissue around it, alone diseased. In fact, when the lining of the artery was removed at the points where any morbid alterations were seen, these were also taken away, and the fibrous tunic left unchanged. In the limb, indeed, where the popliteal aneurism existed, all the arteries were aneurismal, and afforded most convincing evidence of all their coats contributing to the dilations. (See *Breschet, Mém. Chir. sur différentes Espèces d'Aneurysmes*, p. 40, &c.)

While Mr. A. Burns bears testimony to the fidelity and accuracy of Scarpa's general detail, he adds, that perhaps it may not be uniformly found, that "the root of an aneurism never includes the whole circumference of the tube of an artery." We have, says he, a preparation in which the reverse has taken place. In this case, the whole cylinder of the vessel, from the heart to beyond the curvature, is equally dilated; and dilated to such an extent, that the tumor measures no less than ten inches in circumference. Scarpa limits

dilatation, says Mr. Burns, to that state of an artery in which the coats remain in their natural relation to each other, and in which they are not altered in their texture, nor lined on their inner surface with "polypous layers." "This, however, was not the case in the instance which I have brought forward. In it you have seen that the coats were much dilated, and also very much altered in their structure. Externally and internally, they had assumed the look of the membranes of the fœtus, only they were thicker and denser, but they were equally gelatinous, and nearly as transparent; and, on their inner surface, they were crusted over with laminae of coagulated lymph. By peeling off this incrustation, after the sac had been inverted, we saw plainly, that, although the internal coats were, round the complete cylinder of the vessel, much diseased, and considerably dilated, yet they were not dilated in the same degree as the external coverings of the artery. At irregular distances, longitudinal rents were formed in the fibrous coats, and these chasms were filled with coagulating lymph. The internal coats, over the whole circumference of the vessel, had assumed the diseased condition which in aneurism is generally confined to a part of the cylinder. In this tumor, all the coats continued for a time to dilate equally; but at length the internal gave way, forming longitudinal rents, through which the external coats could be seen, after the lymphatic coating had been scraped off. In this instance, had the sac been dissected in the early stage, it would have presented precisely the same appearances as those described by Dr. Monro, and the one (the aneurism) lately examined by the surgical editor of the *London Med. Review*." Mr. Burns afterwards expresses doubts, whether the sac ever acquires a large size without dilatation. The case reported in the latter periodical work was the largest that he knew of, in which all the coats were found uniformly dilated. The sac, which was as large as the fist, was lined throughout with flakes of bone; and though the internal coat of the vessel was thus patched, and extremely thin and brittle, it did not, on minute inspection, anywhere exhibit a solution of continuity. Mr. A. Burns further states, that the above case, reported by himself, was the only one, out of fourteen, which did not corroborate Scarpa's description. (*On Diseases of the Heart, &c.* p. 204.) Mr. Wilson, after mentioning the frequency of aneurism in the aorta, carotid, subclavian, and axillary arteries, and its rarity in the brachial, tells us, that he knows of no example of aneurism below the elbow, where the swelling could not be traced to a wound of the coats of the artery. He adds, that true aneurism has not unfrequently occurred in the internal and external iliac arteries, in the inguinal, femoral, and very frequently in the popliteal. It has taken place in the posterior tibial artery, but he knows of no instance of it in the anterior tibial or peroneal arteries. "I have (says he) met with only one instance of true aneurism affecting any of the branches of the aorta, which are distributed to the abdominal viscera. In the year 1809, on inspecting the body of a clergyman, in the presence of the late Sir. W. Farquhar, a tumor, very much resembling the heart in colour, shape, and size, appeared to hang down from the under surface of the left lobe of the liver. When this tumor was opened, and

carefully inspected, it appeared to have been formed by the left branch of the hepatic artery having become very much enlarged and aneurismal. It had burst, and the blood which had escaped was found in an imperfect cyst, partly in a fluid, and partly in a coagulated state, forming a large proportion of the tumor." (See *Lectures on the Blood, and on the Anatomy, Physiology, and Surgical Pathology of the Vascular System*, p. 379, 380, 8vo. Lond. 1819.)

The facts adduced by Mr. Hodgson appear sufficiently conclusive, and from them the following doctrine is clearly deducible:—

First, That numerous aneurisms are formed by destruction of the internal and middle coats of an artery, and the expansion of the external coat into a small cyst, which giving way from distention, the surrounding parts, whatever may be their structure, form the remainder of the sac.

Secondly, That sometimes the disease commences in the dilatation of a portion of the circumference of an artery. This dilatation increases until the coats of the vessel give way, when the surrounding parts form the sac, in the same manner as when the disease is in the first instance produced by destruction of the coats of an artery. (P. 74.)

The conclusions of Mr. Hodgson are supported by the observations of numerous writers.

The learned Sabatier says, there can be no doubt, that many aneurisms depend upon the dilatation of the arterial coats: but, *in far more numerous examples, the internal tunics are ruptured, and it is the cellular coat alone which separates from them, and enlarges, so as to form the aneurismal sac.*

It is difficult to conceive, he observes, how all the coats of an artery can dilate and yield sufficiently to form the investment of such immense tumors as some aneurisms are. Indeed, that very tunic, which composes the greater part of the thickness of the vessel, and which is termed the *muscular coat*, is known to consist of fibres whose texture is firm, and little capable of bearing extension. However, Haller, in describing a very large aneurism, situated in the aorta, near the heart, relates, that the innermost coat of this vessel was ruptured and torn, the loose jagged edges of the laceration being visible in the aneurismal sac. These were squamous, bony, and of little thickness; while the muscular and cellular coats were quite sound. Donald Monro noticed the same thing in five different aneurisms, in the course of the femoral and popliteal arteries of a man, who had been confined a long while to his bed, after being operated upon for bubonocoele. Monro succeeded in tracing the fibres of the muscular coat over the swellings, so that he had no doubt of this tunic being dilated.

According to Richerand, when an aneurism is recent and of small size, the dissection of the tumor exhibits a simple dilatation of the arterial coats; while, in the other cases, where the aneurism is large, and has existed a considerable time, the internal and middle coats of the vessel are invariably lacerated. In the early stage of the disease, the blood which fills the aneurismal sac is fluid; and, on the contrary, in cases where the internal tunics of the artery are ruptured, the sac contains more or less coagulated lymph. The external or cellular coat composes the greater part

of the cyst; and the coagulated lymph, with which it is filled, is arranged in layers, the density of which is described as being greater in proportion to the length of time which they have been deposited. Such as are nearest the sac are, therefore, most compact, and contain the smallest quantity of the colouring matter of the blood; more deeply, the concretions of lymph resemble simple coagula; and, lastly, the blood, which is still nearer the arterial tube, retains its fluidity.

After the aneurismal sac has been cleansed from the fibrine and coagulated blood which it contains, its parietes will appear to be almost entirely formed of the cellular coat of the artery. Towards the bottom may be observed the aperture, arising from the laceration of the internal and middle coats, which, being much less elastic than the external, are ruptured in an early stage of the disease. It is when these two tunics give way, that the aneurismal tumor undergoes a sudden and considerable increase in its size; for then the cellular coat alone has to sustain all the pressure of the blood, which, now becoming effused into a more ample cyst, loses a great deal of its impetus, coagulates, and forms fibrous masses; circumstances to which may be ascribed the hardness of the swelling, the weakness of its pulsation, &c. (*Nos. Chir. t. iv. p. 82, ed. 2.*)

The reality of true internal aneurisms was insisted upon by C. F. Ludwig, in a programma written expressly on that subject. (*Diagnostices Chir. Fragm. de Aneurysmate Interno*, Lips. 1805.) An interesting case, exemplifying an aneurismal dilatation of all the coats of the abdominal aorta, was published by Professor Nægele of Heidelberg. The swelling was as large as a man's head, and weighed about five pounds. The aorta began to be dilated at the point where it passes into the cavity of the abdomen between the crura of the diaphragm. This dilatation extended gradually down to a point, about four finger-breadths from the bifurcation of the aorta into the iliac arteries, at which point, strictly speaking, the large aneurismal sac commenced. The length of the whole dilated part of the vessel was eleven inches; that of the sac six; and its diameter five inches. The artery was not equally dilated in every direction, the expansion being most considerable laterally and forwards. Nægele and Ackermann found that the three coats of the aorta, the internal, muscular, and cellular, were all equally dilated. These professors traced the muscular coat with the scalpel from the top to the bottom of the tumor, and not the slightest doubt could be entertained that the case was a true aneurism. (*F. C. Nægele, Epistola ad T. F. Baltz, quâ Historia et Descriptio Aneurysmatis, quod in Aorta abdominali observavit, continetur.* Heidelb. 1816.)

In the valuable cases collected by H. F. Janin, convincing evidence will be found of there being one kind of aneurism attended with rupture of the coats of the artery, the cellular coat alone forming the aneurismal sac; and another with an equal dilatation of all the coats of the artery. Of the latter, Janin relates three unequivocal cases. Breschet's investigations, which are supported by the evidence of *post mortem* examinations, leave also no doubt about the truth of aneurism by dilatation, of which he describes not less than four kinds, as already stated, viz. the *aneurisma verum sacciforme*; the *aneurisma verum fusiforme*; the *aneurisma verum*

cylindroidum (comprising aneurism by anastomosis and erectile tumors); and, lastly, the *aneurisma cyrsoideum*, or the *varix arterialis* of Dupuytren; a rarer affection, in which the arteries undergo very similar changes to those exhibited in varicose veins. (*Breschet in Mém. Chir. sur différentes Espèces d'Aneurysmes*, 4to. Paris, 1834.) Lisfranc also admits, with all the best modern surgeons, the reality of aneurism accompanied by dilatation of all the coats of the arteries. (*De l'Oblitération des Artères dans les Aneurismes*, p. 11.)

[Pathologists at present seem to incline to the opinion, that although many of the so-called true aneurisms may not be so in reality, yet that there can be no doubt that, in their early stages at least, many aneurisms are of the true kind. Dr. Peacock has pointed out, that small digital pouches are often found springing from the walls of some of the large arteries, through the whole extent of which the external, middle, and internal coats can be demonstrated to exist. After an aneurism has attained a certain size, its coats become so fused together, and so incorporated with the neighbouring tissues, that the true juncture cannot be made out. For a true aneurism to exist, I am of opinion that two conditions are necessary: first, that the tumor be small; second, that the mouth of the sac be large. I cannot conceive a large aneurism with a small mouth to be a true one, for as the mouth of the sac corresponds exactly in size to that portion of the arterial coats that has been dilated, it is not easy to understand how a large sac can be dilated out of a small segment of the wall of the artery, though there be some outgrowth of this, as in tubular aneurism.]

When these two different affections are situated in the thorax, or abdomen, it is impossible to discriminate them from each other before death. The symptoms, occasioned by the pressure of the tumor on the viscera must be nearly the same, whether caused by a morbid dilatation, or an aneurism. The means for retarding their fatal termination is also the same in both forms of the disease. With regard to the possibility of cure, however, Scarpa says, that there is great difference; for, when the case is an internal aneurism, there may be some slight hope of a radical cure by the efforts of nature and art, which hope can never be entertained in a case of morbid dilatation; a fact which is accounted for by no laminated coagula being deposited in the latter disease. (*On Aneurism*, transl. by Wishart, p. 124, ed. 2.) A great deal of the latter statement coincides with the observations of Mr. Hodgson, who particularly notices, that he has never met with lamellated coagula in such sacs as consist either in a general or partial dilatation of the coats of the vessel. (*On Diseases of Arteries*, &c. p. 82.) Whether this ever takes place in such cases may still be a question, because, if Professor Nægele has given a correct description of the aneurism of the abdominal aorta, already mentioned—which aneurism was of large size, and consisted of a dilatation of all the coats of the vessel—there was in this rare example a large quantity of these layers of coagulated blood. Yet, whether the Professor actually means the fibrine arranged in laminae, or only common coagulated blood, which, as every one knows, may be found either in the cysts of dilated or of ruptured arteries, may admit of doubt. The statement, therefore, made by Hodgson and

Scarpa, and which agrees with the later observations of Breschet (see *Mém. Chir. sur différentes Espèces d'Aneurismes*, p. 70), may not be contrary to what was really seen by Nægele and Ackermann. The following case, however, observed by Laennec, and quoted by a modern writer, must (if correctly reported) afford not only an unequivocal specimen of aneurism by dilatation of all the coats of the aorta, but of laminated coagula within its cavity. “In homine enim, qui repente sub atrocissimis pectoris doloribus corruit, præter aortam adscendentem in aneurysma ita expansam, ut neonati infantis caput æquaret, cystidem aneurysmaticam immediatè suprâ arteriæ cœliacæ ortam magnitudine nucis juglandis invenit, quæ luculenter ostendit sinum communicantem cum arteriæ cylindro per foramen magnitudine amygdalæ, diametro totius arteriæ illo loco non mutato. Saccus hic cultro anatomico accuratè ac subtiliter subjectus, eandem structuram, easdem ostendit membranas, quibus gaudebat arteria e cujus latere excreverat; cæterum massis grumosis sive fibrosis erat impletus. Inde igitur patet, hoc aneurysma sacciforme et laterali et partiali quidem tunicarum aortæ dilatatione ortum esse.” (*J. H. G. Ehrhardt, De Aneurysmate Aortæ*, p. 13, 4to. Lips. 1820.)

Certainly, it seems difficult to explain in what the difference consists, which prevails between the state of the internal coat, in *preternatural* dilatation, and in *true* aneurism, so that the blood does not coagulate in the former, while it is deposited in concentric layers in the latter. (See *Guthrie, On Dis. of the Arteries*, p. 85.) Perhaps, says the latter gentleman, there is not at a late period any difference between a preternatural dilatation or bulging on one side of an artery, and a true aneurism; a state remarkably well shown in one of the preparations in the College Museum, No. 411 H.; and he adds, “At all events, preternatural dilatations of a large size, and departing from the course of the vessel from which they arise, do generally lose their distinguishing character of freedom from concentric layers of coagula, so that the distinction between them, under these circumstances, is lost;” unless we regard it, with Scarpa, as essentially founded on the existence of fissures in the internal coat in the aneurism, and of the absence of such change in the simple dilatation.

[The reason why coagulum is not deposited in a preternatural dilatation of an artery, would appear to be, that in no part of the tumor is the blood at rest or out of the current of the circulation, so as to allow it time to deposit its fibrine; whereas, in a sacculated aneurism, it is withdrawn from the general circulation, and thus has time for a coagulum to form.]

From what has been stated then, it appears that there is only one principal point of difference between Scarpa and other writers; and this resolves itself into the question, whether a dilatation of an artery, arising at one particular side of the vessel, and lined by its internal coat, ought not to be regarded as an aneurism, because its communication with the tube of the artery is more capacious than what exists in other aneurisms, where the inner coat has given way, and because it rarely (perhaps never) contains laminated coagula, unless fissures happen to exist at some points of the inner arterial tunic thus expanded?

The greater number of aneurisms increase gra-

dually, and sooner or later incline to the side on which the least resistance is experienced. De Haen mentions an aneurism of the aorta, which first made its appearance between the second and third ribs of the left side, and which, instead of growing larger, as is usual, subsided, and could neither be seen nor felt, for more than a month before the patient's decease, although, on opening the body, a tumor of the arch of the aorta was found, three times as large as the fist. De Haen imputes the sudden disappearance of the swelling to its weight, the yielding of the parts with which it was connected, and to its gravitating into the chest when the patient lay on his right side; for the difficulty of breathing, and other complaints, produced by the pressure on the lungs, underwent a material increase as soon as the tumor ceased to protrude.

The pulsations, which accompany true aneurisms, continue to be strong, until the inner coats of the vessel give way, or the layers of coagulated blood lodged in the sac are numerous. Hence, when soft swellings, situated near any large arteries, lose their pulsatory motion, their course, precise situation, and other circumstances, ought to be most carefully investigated before any decision is made about the mode of treatment.

[Together and synchronous with the pulsation, there is a bruit in the aneurismal sac, usually of a bellows, sawing, or rasping character. This is most intense when the aneurism is soft, but diminishes in distinctness as the tumor becomes consolidated by the deposit of laminated fibrine within it. It is loudest opposite the mouth of the sac, and ceases when the flow of blood through the tumor is arrested by the compression of the artery leading to it.]

In many instances, the most fatal accidents have happened, in consequence of incisions having been made in aneurisms, which were mistaken for abscesses, because there was no pulsation. Vesalius was consulted about a tumor of the back, which he pronounced to be an aneurism. Soon afterwards, an imprudent practitioner made an opening in the swelling, and the patient bled to death in a very short time. Ruysch relates, that a friend of his opened a tumor near the heel, not supposed to be an aneurism, and the greatest difficulty was experienced in suppressing the hemorrhage. De Haen speaks of a patient, who died in consequence of an opening, which had been made in a similar swelling at the knee, although Boerhaave had given his advice against the performance of such an operation. Palfin, Schlitting, Warner, Dupuytren, and others, have recorded mistakes of the same kind. (*Sabatier*, t. iii. p. 167.) Ferrand, surgeon of the Hôtel Dieu, mistook an axillary aneurism for an abscess, plunged his bistoury into the swelling, and killed the patient. "*J'ai été témoin d'erreurs semblables, commises par les praticiens non moins fameux; et si des anéurismes externes on passe à ceux des artères placées à l'intérieur, les erreurs ne sont ni moins ordinaires ni de moindre conséquence.*" (*Richerand*, *Nosogr. Chir.* t. iv. p. 75, ed. 2.)

Notwithstanding a pulsation is one of the most prominent symptoms of an aneurism, it is not to be inferred, that every swelling which pulsates is unquestionably of this description; for, as Mr. Warner has explained, it does happen that mere imposthumations, or collections of matter, arising

from external as well as internal causes, are sometimes so immediately situated upon the heart itself, and at other times upon some of the principal arteries, as to partake, in the most regular manner, of their contraction and dilatation. He details the particulars of a boy, about thirteen years of age, whose breast-bone had been badly fractured, and who was admitted into Guy's Hospital a fortnight after the accident had happened. The broken parts of the bone were removed some distance from each other. The intermediate space was occupied by a tumor of a considerable size; the integuments were of their natural complexion. The swelling had as regular a contraction and dilatation as the heart itself, or the aorta could be supposed to have. Upon pressure, the tumor receded; upon a removal of the pressure, the tumor immediately resumed its former size; all these are allowed to be distinguishing signs of a recent true aneurism. The situation and symptoms of this swelling were judged sufficient reasons for considering the nature of the disease as uncertain; on which account it was left to take its own course. The event was, the tumor burst in about three weeks after his admission; discharged a considerable quantity of matter; and the patient did well by very superficial applications. (*Cases in Surgery*, ed. 4, p. 155.)

[The diagnosis of pulsating tumors of bone, whether encephaloid or not, from aneurism, is attended by no little difficulty. In many cases, the situation of the tumor, away from any large arterial trunk, its incompressibility, irregular outline, and firmer connection, or rather incorporation, with the bone, will enable the surgeon to avoid the error of confounding it with an aneurism. But in other instances, when seated at the brim of the pelvis, in the gluteal region, or in other situations where aneurisms are apt to occur, the greatest difficulty will occur, and the most experienced surgeons have erred in their diagnosis, and have ligatured the artery, on the supposition that they had to do with an aneurism, when, in reality, it was a case of pulsating tumor of bone. It may be observed, that these pulsating osseous growths are chiefly connected with the heads of the long bones.]

Under certain circumstances, a psoas abscess may be mistaken for an aneurism; as, for instance, when it occasions a small, soft, moveable swelling over the femoral artery in the groin, accompanied by a strong pulsatory motion. The tumor may be lessened by pressure, even in the erect position, and rapidly returns on the discontinuance of such pressure, as would be the case in aneurism. The pulsation is manifest; but, after the swelling has been lessened by pressure, its sudden resumption of size in the erect position is not accompanied by the peculiar pulsatory thrill felt in an aneurism. In a psoas abscess, the swelling does not return in the same degree on the removal of the pressure, as in a case of aneurism. During the retrocession of the purulent fluid, the course of the artery may be more readily examined. In cases of psoas abscess, the swelling has generally been preceded by pains in the back and loins, of some standing, which continue with weakness of one or both extremities. (See *Guthrie*, *On Dis. of Arteries*, p. 120.)

As Mr. Wilson has observed, any encysted, or even solid tumor, situated in the neighbourhood

of, or upon, a large artery, may have a considerable degree of motion communicated to it from the pulsation of the artery. The thyroid gland, when a bronchocele is formed, occasionally receives a pulsatory motion from the carotid arteries. This may be mistaken for an aneurism; from which disease, however, it can be discriminated by placing our fingers behind the tumor, and drawing it forwards, when the pulsation ceases. But there are other criteria for distinguishing a swelling, on or near an artery, from an aneurism. In such a case the whole tumor moves at once, without any alteration of size. In an aneurism, the swelling does not simply move, it expands. A tumor of the thyroid gland, having apparently a pulsatory motion, may be known not to be an aneurism of the carotid, by observing, that, from its connection with the larynx, it follows the movements of the latter in deglutition. Aneurisms, not of very long standing, and not containing a large mass of laminated coagula, may also be diminished, or rendered more or less flaccid, by pressing the artery leading to the disease. (See *Wilson on the Blood, Anatomy, Pathology, &c. of the Vascular System*, p. 385; and *Burns on the Heart*, p. 257.) In cases of much ambiguity, the stethoscope will sometimes convey the necessary information. In a doubtful instance of aneurism of the groin, Sir Benjamin Brodie found all obscurity cease on the application of this instrument. (*Sir A. Cooper's Lectures*, vol. ii. p. 46.)

Whenever an aneurism of immoderate size beats strongly, and for a long while, against the bones, as the sternum, ribs, clavicle, and vertebræ, they are in the end injured or destroyed, the aneurismal tumor elevating the integuments of the thorax, or back, and pulsating immediately under the skin. Scarpa, with the best modern writers, attributes the effect to absorption, in consequence of the pressure.

[The pressure effects of aneurisms are important. Accompanying veins are narrowed, thickened, and even obliterated. Arterial trunks in the neighbourhood of the tumor may be obliterated by its pressure, as sometimes happens at the back of the neck, or eroded and opened, as I have seen happen in the pulmonary artery from an aortic aneurism; or the parent trunk itself may be obliterated by the pressure of the sac. Nerves are stretched and rendered tortuous, waving, or are flattened out into ribbon-like expansions. Organs suffer serious interruptions to their functions, and the elimination of their secretions may be interfered with by the compression of their ducts. By pressure on the trachea and œsophagus respiration and deglutition may be seriously impeded. The bones become eroded, and if flat may be perforated by as smooth and circular an aperture as if cut by the trephine.]

The carious and corroded state of the bones in aneurism is never attended with the formation of pus; "at least, the discovery of pus in its vicinity has not been remarked by those who have examined such cases. In this respect, therefore, it differs essentially from common caries, or ulceration of bones. Exfoliation also is very rarely attendant upon it: from which circumstance, one important practical observation is deducible, namely, that if the aneurism be cured, the bones will recover their healthy state, without undergoing

those processes which take place in the cure of caries or necrosis. (See *Hodgson, On the Dis. of Arteries and Veins*, p. 80.) That this process of absorption in bone, in consequence of the pressure of an aneurism, may be caused by other tumors, is finely exemplified in a thigh-bone preserved in the Museum of University College. The bone has been reduced by the pressure of a tumor, which grew at the back of the limb, to a mere spindle, that has not been able to resist the efforts of the muscles, by which it has been twisted in a singular degree. The absorption of bone from the pressure of aneurisms, is of that description, termed by Mr. Hunter *progressive*, in which, as Mr. Guthrie observes, the action of the small arteries, necessary to constitute inflammation, is wanting, and consequently there is little comparative pain at the commencement of the process, and no formation of matter. (See *Guthrie, On Diseases of Arteries, &c.* p. 57.)

Mr. Hodgson confirms the remark made by Dr. W. Hunter (*Med. Obs. and Inquiries*, vol. i. p. 384), Scarpa (*On Aneurism*, p. 100, ed. 2), and others, that cartilage is less rapidly destroyed by the pressure of an aneurism than bone. This fact is strikingly illustrated in a case of aneurism of the thoracic aorta recorded in another modern publication: the bodies of the vertebræ, from the fourth down to the ninth were carious; the four lowest in particular; yet the intervertebral cartilages were not materially affected. (*F. L. Kreysig, Die Krankheiten des Herzens*, b. iii. p. 176, 8vo. Berlin, 1817.) In the Museum of University College are fine specimens of the perfect state of the intervertebral substance, though the bodies of the vertebræ have greatly suffered.

A case is related by Pelletan, to which I refer the reader, as exemplifying not only the degree, in which internal aneurisms may injure the vertebræ, but also the occasional possibility of such diseases being mistaken for rheumatism, or a lumbar abscess. (See *Clinique Chir.* t. i. p. 97—100.)

CAUSES OF ANEURISM.

An aneurism will not follow the kind of weakness of the sides of an artery, which must necessarily arise from removing its external and middle coat, some morbid changes seeming to be essential to bring on a protrusion of the inner coat. Neither will a mechanical division of the inner tunics lead to an aneurismal dilatation of the outer coat. The latter fact is proved by what happens when a tight ligature is placed upon an artery, as well as by the experiments of M. Amussat who purposely broke the internal coats in numerous places, by pinching the vessels with forceps, and detaching the inner coats from the outer, by a process somewhat similar to what he adopts in torsion of the arteries. By proceedings of this kind, he never succeeded in producing the beginning of an aneurism. The inference, therefore, is, that some description of morbid change in the coats of the artery is necessary for the formation of aneurism, so long as the occurrence is resisted by a perfect state of one of those coats; or else we must arrive at the still more certain conclusion, that in the experiments undertaken by Hume, Amussat, and others, the irritation of the artery was followed by inflammation of it, coagulation of the blood, and such an effusion of fibrine, within and

around it, as would fully account for no aneurismal tumor being the result.

One very interesting point, in relation to spontaneous aneurism, and particularly adverted to by M. Malgaigne, is the almost exclusive restriction of this disease to the aortic system. Thus, in more than three hundred aneurisms, observed by M. Lisfranc, or recorded by others, he has met with only two instances of an aneurismal disease of the pulmonary artery, and these not free from objection. (*Lisfranc, Des diverses Méthodes, &c. pour l'Oblitération Des Arteres*, p. 8, 8vo. Paris, 1834.) This remarkable fact is suspected to depend upon the aortic arteries containing, between their inner and fibrous coats, a dense, hard, fragile tissue, only capable of being taken off in scales, and designated by M. Malgaigne the *sclerous* coat. When concretions of different kinds, calcareous, steatomatous, or cartilaginous, present themselves in the aorta, they are seated, according to M. Malgaigne, almost exclusively, in this sclerous coat, a texture not existing in the pulmonary artery or its branches.

In many instances, it is difficult to assign any cause for the commencement of aneurism. Among the circumstances which predispose to the disease, however, the large size of the vessels may undoubtedly be reckoned. Those trunks which are near the heart have much thinner parietes, in relation to the magnitude of the column of blood with which they are filled, than arteries of smaller diameter; and since the lateral pressure of this blood against the sides of the arteries is in a ratio to the magnitude of these vessels, it follows, that aneurisms must be much more frequent in the trunks near the heart, than in such as are remote from the source of the circulation. (*Richerand, Nosogr. Chir.* t. iv. p. 72, edit. 2.) The whole arterial system is liable to aneurisms; but, says Pelletan, experience proves, that internal arteries are much more frequently affected, than such as are external. (*Clinique Chir.* t. i. p. 54.)

The curvatures of the arteries are another predisposing cause of the disease, and have a manifest effect in determining the formation of the great sinus of the aorta, the dilatation which exists between the arch and the origin of this large artery, and which is the more considerable the older the person is: Monro even thought, that one half of old persons have an aneurism at the beginning of the aorta. And with respect to aneurisms in general, which are preceded by calcareous depositions, thickening, and disease of the coats of the vessel, they are most frequent in persons of advanced age. Aneurisms from wounds are of course often seen in individuals of every age. In old people, the coats of the arteries are subject to a disease, which renders them incapable of making due resistance to the lateral impulse of the blood. The disease here alluded to is what is described in a foregoing part of this article; one common effect of which is the deposition of calcareous matter between the inner and muscular coats of the arteries, or in the sclerous coat of Malgaigne. "People in the early part of life," says Mr. Wilson, "are not very subject to these calcareous depositions; but, I have occasionally met with them in the arteries of very young people. I have seen a well-marked deposition of the phosphate of lime in the arteries of a child under three years of age." He adds, that few persons, above

the age of sixty, are free from these ossifications. (*On the Blood, and on the Anatomy, Pathology, &c. of the Vascular System*, p. 375. Lond. 1819.)

[Cachexy, in whatever way induced, whether by mercury or syphilis, disposes to aneurism by inducing those structural changes in the arterial coats that ultimately lead to their dilatation.]

According to Sir Astley Cooper, the time of life when aneurism generally occurs, is between the ages of thirty and fifty; an age, when exercise is considerable, and strength on the decline. In very old age the disease is not so common. However, he operated successfully on a case of popliteal aneurism, where the patient was eighty-four, or eighty-five years old. He operated, with success, on another man, sixty-nine years of age. He has also seen a boy, only eleven years old, with aneurism of the anterior tibial artery. The man of more than eighty is the oldest, and the boy of eleven the youngest, aneurismal patient he has ever seen. (See *Lectures*, vol. ii. p. 40.)

On the subject of the comparative frequency of aneurism at various periods of life, M. Lisfranc refers to 120 cases, in which the age of the patient is specified, and from which he drew up the annexed table:—

Age.	Cases.	Age.	Cases.
13	- 1	40 to 45	- 20
15 to 20	- 3	45 to 50	- 17
20 to 25	- 5	50 to 55	- 11
25 to 30	- 12	55 to 60	- 6
30 to 35	- 24	60 to 70	- 3
35 to 40	- 15	70 to 80	- 3

Thus, M. Lisfranc finds, what Sir Astley Cooper had ascertained long ago, that aneurisms are most common between the ages of thirty and fifty: that ten years on one side or the other of these ages make a remarkable difference,—under twenty, and after sixty, the disease being exceedingly rare. Aneurisms by anastomosis, however, which are entirely a different affection from the cases now under consideration, are chiefly met with in children and young persons under fifteen, and seldom in adults. M. Lisfranc knows of no example of aneurism by anastomosis in an old person. (*De l'Oblitération des Artères, &c.* p. 12, 13.)

Richerand affirms, that, out of twelve popliteal aneurisms, which he had seen in hospital or private practice, ten were caused by a violent extension of the leg. This statement, he says, will derive confirmation from the following experiment. Place the knee of a dead subject on the edge of a firm table, and press on the heel, so as forcibly to extend the leg, far enough to make the ligaments of the ham snap. Now dissect the parts, cut out the artery, and examine its parietes in a good light, when the lacerations of the middle coat will be observable, and rendered manifest by the circumstance of those places appearing semitransparent, where the fibres are separated, the parietes at such points merely consisting of the internal and external tunics. (*Nosogr. Chir.* t. iv. p. 73, 74, ed. 2.) But the insufficiency of this explanation is clear enough from the fact, that such violence as is requisite to break the ligaments of the knee, cannot be imagined to happen in the accidents which ordinarily bring on aneurism in the ham.

The implicit belief of Richerand, that the la-

ceration of the middle coat of an artery will bring on an aneurism, while the inner coat is perfect, will appear to be unfounded, when Amussat's experiments are remembered, and also those of Hunter, Home, and Scarpa, who even dissected off the external and middle coats of arteries, without being able in this manner to cause an aneurism. Nay, where the experiment has been made of applying a tight ligature to an artery, and immediately removing it again in order to determine whether the division of both the inner coats of the vessel would terminate in an obliteration of the tube of the vessel, no aneurism has been the consequence.

Pelletan accounts for the frequency of popliteal aneurisms somewhat differently from Richerand: speaking of the two principal motions of the knee, viz. extension and flexion, he remarks, that the first of these is so limited, that it is actually an incipient flexion necessarily produced by the curvature backward both of the condyles of the femur and those of the tibia. This curvature, which would seem to protect the popliteal artery against any dangerous elongation, that might otherwise be caused by a forcible extension of the joint, becomes the very source of such an elongation in persons who are accustomed to keep their limbs bent, or who, from this state, proceed hastily and violently to extend the leg. The arterial tubes are really shortened, when the limbs are in the state of flexion, and lengthened, when the extension of the members renders it necessary. Hence, says Pelletan, it is manifest, that an habitually shortened state of these vessels, and their sudden elongation, must be attended with hazard of rupturing their parietes. (*Clinique Chirurgicale*, t. i. p. 112.)

The opinion of Pelletan, however, is quite untenable: because Mr. Hodgson has several times repeated the experiment mentioned by Richerand, and found, as this gentleman did, that the coats of the artery were never lacerated, unless the degree of violence had been such as to rupture the ligaments of the knee. (*On Diseases of Arteries*, &c. p. 64.)

Aneurisms are exceedingly common in the aorta, and they are particularly often met with in the popliteal artery. The vessels which are next to these most usually affected, are the crural, common carotid, subclavian, and brachial arteries. The temporal and occipital arteries, and those of the leg, foot, forearm, and hand, are far less frequently the situations of the present disease. But, although it is true, that the larger arteries are the most subject to the ordinary species of aneurisms, the smaller arteries seem to be more immediately concerned in the formation of one peculiar aneurismal disease, now well known by the name of *aneurism by anastomosis*, of which I shall hereafter speak.

According to surgical writers, the causes of aneurisms operate either by weakening the arterial parietes, or by increasing the lateral impulse of the blood against the sides of these vessels. It is said to be in both these ways, that the disease is occasioned by violent contusions of the arteries, the abuse of spirituous drinks, frequent mercurial courses, fits of anger, rough exercise, exertions in lifting heavy burthens, &c. In certain persons aneurisms appear to depend upon a particular organic disposition. Of this description was the

subject whose arteries, on examination after death, were found by Lancisi affected with several aneurisms of various sizes. I have known a person have an aneurism of one axillary artery, which disease got spontaneously well, but was soon afterwards followed by a similar swelling of the opposite axillary artery, which proved fatal. I have seen another instance, in which an aneurism of the popliteal artery was accompanied with one of the femoral in the other limb. Boyer mentions a patient, who died of a femoral aneurism in La Charité, at Paris, and who had also another aneurism of the popliteal artery, equal in size to a walnut. (*Traité des Maladies Chir. &c.* t. ii. p. 102.) The greatest number of aneurisms that Sir Astley Cooper has seen in one patient is seven; and it is a remark made by this eminent surgeon, that when an aneurism occurs in the ham, the disease is frequently of a local nature; but that, when it is between the groin and ham, disease of other arteries is very commonly met with. (See *Lectures*, vol. ii. p. 37.) One memorable case, proving the existence of a disposition to aneurisms in the whole arterial system, is mentioned by Pelletan: "J'ai pourtant vu plusieurs fois ces nombreux aneurismes occupants indistinctement les grosses ou les petites artères, mais surtout celles de capacité; j'en ai compté soixante-trois sur un seul homme, depuis le volume d'une aveline jusqu'à celui de la moitié d'un œuf de poule." (*Clinique Chir.* t. ii. p. 1.) M. Jules Cloquet relates a case, in which all the arteries were covered with aneurismal tumors, from the size of a hemp-seed to that of a large pea. Some existed on the aorta; but larger numbers on the arteries of the limbs. Altogether, there were some hundreds of them. Excepting in the situations of the tumors, the structure of the arterial coats had undergone no alteration. Here they were dilated and thinned. In none of them was any rupture of the internal or middle coat observed. The dilatations were continued into the small arteries, in which, however, they were less conspicuous than in those of superior size. (See *J. Cloquet, Pathologie Chir.* p. 86, pl. 2. 4to. Paris, 1831.) These aneurisms corresponded to the sacciform aneurisms of Breschet.

Aneurisms, and those diseases of the coats of arteries which precede the formation of aneurism, are much less frequently met with in women than in men. (*Lassus, Pathologie Chir.* t. i. p. 348.) A few years before John Hunter died, Mr. Wilson heard him remark, that he had only met with one woman affected with *true* or spontaneous aneurism. (*Anatomy, Pathology, &c. of the Vascular System*, p. 376.) The influence of the periodical loss of blood, during menstruation, on the vascular system of the female has not been sufficiently considered in reference to the less frequent occurrence of aneurism in women than in the opposite sex. Doubtless the relief from over distention enjoyed by the bloodvessels during the middle period of life in females, when the catamenia are present, is one of the principal causes of the difference observed in the liability to this disease in the two sexes. Mr. Hodgson drew up the following table, exhibiting the comparative frequency of aneurisms in the two sexes, in different cases of this disease, and also in the different arteries of the body, as deduced from examples, either seen by himself, during the lives of the patients, or soon after their death:—

	Total.	Males.	Females.
Of the ascending aorta, the arteria innominata, and arch of the aorta -	21	16	5
Descending aorta -	8	7	1
Carotid artery -	2	2	0
Subclavian and axillary -	5	5	0
Inguinal artery -	12	12	0
Femoral and popliteal -	15	14	1
	63	56	7

This table does not include aneurisms arising from wounded arteries, nor aneurisms by anastomosis. (*On the Diseases of Arteries and Veins*, p. 87.) Sir Astley Cooper confirms the fact of the much greater frequency of aneurism in the male than the female sex. Women, he says, rarely have aneurism in the limbs. In forty years' experience, he has seen only eight cases of popliteal aneurism in women, but an immense number in men. Most of the aneurisms, which he has seen in females, have been in the ascending aorta, or the carotids. (*Lectures*, vol. ii. p. 41.) Mr. Guthrie has met with but three popliteal aneurisms in women; and he calculates that aneurism of the ham occurs from twenty to thirty times in men for once in women. "The structure of the vessels (he observes) is the same, but the mode of life is different. The exertion in general is infinitely greater in the man than the woman; and I think this, combined with the freer use of ardent spirits, a much more likely cause than either syphilis or mercury." (*On Dis. of Arteries*, p. 87.)

In relation to the comparative frequency of aneurism in the two sexes, M. Lisfranc states, that in 154 cases, the particulars of which have been collected by him, and whose situations brought them within the reach of operative surgery, the proportion of male patients was 141; of females 13; or nearly as 11 to 1.

[Crisp states, that of 551 aneurisms of all kinds, seven-eighths occurred in men. It is interesting to observe, however, that this proportion does not hold good for all aneurisms. Thus, those of the carotid are as frequent in women as in men, whilst of all other aneurisms, there are 18 in men to 1 in women. Dissecting aneurisms are more frequent in women.]

With respect to the comparative frequency of aneurism in different arteries, M. Lisfranc refers to 179 cases, all spontaneous, those of the aorta not entering into the computation; from which 179 cases he gives the following table:—

1. Popliteal artery -	-	-	59
2. Femoral { in the groin -	-	-	26
{ at other points -	-	-	18
3. Carotid -	-	-	17
4. Subclavian -	-	-	16
5. Axillary -	-	-	14
6. External iliac -	-	-	5
7. Brachio-cephalic -	-	-	4
8. Brachial -	-	-	3
9. Common iliac -	-	-	3
10. Anterior tibial -	-	-	3
11. Gluteal -	-	-	2

12. Internal iliac -	-	-	2
13. Temporal -	-	-	2
14. Internal carotid -	-	-	1
15. Ulnar -	-	-	1
16. Peroneal -	-	-	1
17. Radial -	-	-	1
18. Palmar arch -	-	-	1

It was observed by Morgagni, and it has been noticed in this country, that popliteal aneurisms occur with particular frequency in postilions and coachmen, whose employments oblige them to sit a good deal with their knees bent. In France, the men who clean out dissecting-rooms and procure dead bodies for anatomists, are said almost all of them to die of aneurismal diseases. Richerand remarks, that he never knew any of these persons who were not addicted to drinking. (*Nosogr. Chir.* t. iv. p. 74, ed. 2.)

Aneurisms are supposed by M. Roux to be much more frequent in England than in France; a circumstance which he refers to the mode of life and kind of labour, to which a large part of the population of England is subjected. Indeed, he connects this surmise with a reason for the very cultivated state of this part of knowledge in England; thinks that we have been placed in favourable circumstances for perfecting the treatment of aneurisms; and acknowledges, that we have contributed more than his countrymen, both in the last and present century, to the improvement of this branch of surgery. (*Roux, Parallèle de la Chirurgie Angloise avec la Chirurgie Française*, &c. p. 249.)

In some instances, axillary aneurisms seem to have arisen from violent extension of the limb. (See *Pelletan, Clinique Chir.* t. ii. p. 49, and 83.) In other examples, related by the same practical writer, aneurism arose from reiterated contusions and rough pressure on parts. (*Op. cit.* p. 10, and 14. Also *Guthrie, On Dis. of Arteries*.)

The extremity of a fractured bone may injure an artery, and give rise to an aneurism; instances of which are recorded by Pelletan (*Op. cit.* t. i. p. 178), and Duverney (*Traité des Mal. des Os*, t. 1). In Pelletan's case, the disease followed a fracture of the lower third of the leg. An aneurism of the anterior tibial artery, from such a cause, is also described by Mr. C. White. (*Cases in Surgery*, p. 141.)

The following case of an aneurism of the humeral artery after amputation, is recorded by Warner:—C. D. was afflicted with a caries of the joint of the elbow, which was attended with circumstances rendering amputation necessary. The operation was performed at a proper distance above the diseased part, and the vessels were taken up with needles and ligatures.—In a few days, the humeral artery became so dilated above the ligature upon it, as to be in danger of bursting. Hence it was judged necessary to perform the operation for the aneurism, which was done, and the vessel secured by ligature, above the upper extremity of its distended coats. Every thing now went on for some time, exceedingly well; when suddenly the artery again dilated, and was in danger of bursting above the second ligature. These circumstances made it necessary to repeat the operation for the aneurism. From this time every thing went on successfully, till the stump was on the point of being healed; when, quite unexpectedly, the artery appeared a third time

diseased in the same manner as it had been previously, for which reason, a third operation for aneurism was performed, followed by no relapse. "Could the several aneurisms of the humeral artery (says Mr. Warner) be attributed to the sudden check alone, which the blood met with from the extremity of the vessel being secured by ligature? or is it not more reasonable to suppose, that the coats of the artery, nearly as high up as the axilla, were originally diseased and weakened?" The latter seemed, to this judicious writer, the most probable way of accounting for the successive returns of the disease of the vessel: since it is found from experience, that such accidents have been very rarely known to occur after amputation either of the arm or thigh, where nearly the same resistance must be made to the circulation in every subject of an equal age and vigour, who has undergone such operation. If it were supposed, that the several dilatations of the coats of the vessel arose merely from the check in the circulation, it appeared to Mr. Warner not easy to account for the final success of this operation; especially when we reflect, that the force of the blood is increased in proportion to its nearness to the heart. (See *Cases in Surgery*, p. 139, 140, ed. 4.) Ruysch has related an observation somewhat similar. (*Obs. Anat. Chir.* t. i. p. 4.) In 1813, M. Roche published another occurrence of this kind, which happened in the posterior tibial artery. (See *Lisfranc, De l'Oblitération des Artères*, p. 97.)

PROGNOSIS.

In cases of aneurism, the prognosis varies according to a variety of important circumstances. The disease may generally be considered as exceedingly dangerous; for, if left to itself, it almost always terminates in rupture, and the patient dies of hemorrhage. There are some examples, however, in which a spontaneous cure took place; and aneurismal swellings have been known to lose their pulsation, become hard, smaller, and gradually reduced to an indolent tubercle, which entirely disappeared. After death, the artery, in such instances, has been found obliterated, and converted into a ligamentous cord, without any vestige of the aneurism being left. Aneurisms are also sometimes attacked with mortification; the sac and adjacent parts slough away; the artery is closed with coagulum; and thus a cure is effected. Lastly, tumors, having all the characters of aneurisms, have been known to disappear under the employment of such pressure as was certainly too feeble to intercept entirely the course of the blood. Such examples of success, however, are not common; and whenever they happen, it is because the entrance of blood into the sac is prevented by the coagulation of that already contained in it, and because the artery above the swelling is filled with coagulum. They must, in fact, have been cured on the very same principle which renders the surgical operation successful.

[The way in which the spontaneous cure of an aneurism takes place has been especially investigated of late years by Mr. Bellingham. It occasionally, but very rarely happens, that in consequence of inflammation the sac becomes consolidated, and the artery obliterated. But more frequently the spontaneous cure takes place by the

deposition in the interior of the sac, of successive layers of laminated fibrine, by which the flow of blood through the sac is partially interfered with, until at length it is completely interrupted. This process is most commonly met with in arteries of the second and third order of magnitude; never, I believe, in the aorta. It can only occur in sacculated aneurisms, and is much favoured by any circumstance that diminishes the force and lessens the amount of blood passing through the sac.]

Nothing is subject to more variety than the duration of an aneurism previously to its rupture; the tumor bursting sooner or later, according as the patient happens to lead a life of labour, or ease, temperance, or moderation. [Even the bursting of an internal aneurism may not immediately kill the patient. There is usually hemorrhage for some hours or days from an aneurism about to give way, before the final rupture takes place, and the fatal event may be retarded for weeks by the accidental plugging up of the orifice in the sac by a coagulum. Aneurisms prove fatal very frequently by their *pressure effects*. The compression exercised by an aneurism of the arch of the aorta upon the vagus nerve, upon the trachea, or bronchi may occasion fatal results.]

Every aneurism so situated that the artery can neither be compressed, nor tied above the swelling, has generally been considered absolutely incurable, except by a natural process, the establishment of which is not sufficiently often the case to raise much expectation of a recovery on this principle. But it should be recollected, that sometimes the size of the swelling appears to leave no room for the application of a ligature above it, while things are in reality otherwise, in consequence of the communication between the sac and the artery bearing no proportion to the magnitude of the tumor itself. At the present day, also, enlightened by anatomical knowledge, and encouraged by successful experience, surgeons boldly follow the largest arteries, even within the boundaries of the chest and abdomen, as I shall presently relate; and numerous facts have now proved, that few external aneurisms are beyond the reach of modern surgery. It being certain, that aneurisms cannot be commonly cured, except by an obliteration of the affected artery, it follows, that the circulation must be carried on by the superior and inferior collateral branches, or else the limb would mortify. Experience proves, that the impediment to the passage of the blood through the diseased artery, obliges this fluid to pass through the collateral branches, which gradually acquire an increase of size. It is therefore a common notion, that it must be in favour of the success of the operation, if the disease be of a certain standing; and, in direct opposition to the sentiments of Kirkland, Boyer even asserts, that the most successful operations have been those performed on persons who have had the disease a long while. (*Maladies Chirurg.* t. ii. p. 116.)

There is this objection to delay, however,—the tumor becomes so large, and the effects of its pressure so extensive and injurious, that, after the artery is tied, great inflammation, suppuration, and sloughing, often attack the swelling itself, and the patient falls a victim to what would not have occurred had the operation been performed sooner.

The large size of an aneurism, as Mr. Hodg-

son has rightly observed, is a circumstance which materially prevents the establishment of a collateral circulation. When the tumor has acquired an immense bulk, it has probably destroyed the parts in which some of the principal anastomosing branches are situated; or by its pressure it may prevent their dilatation. (*On the Diseases of Arteries and Veins*, p. 259.) The practice of permitting an aneurism to increase, that the collateral branches may become enlarged (says this gentleman), is not only unnecessary but injurious, inasmuch as the increase of the tumor must be attended with a destruction of the surrounding parts, which will render the cure of the disease more tedious and uncertain. (P. 266.)

The most successful operations which I have seen, were performed before the aneurismal swellings were large. However, notwithstanding the great disadvantages of letting the swelling become bulky before the operation, the fact has not always made due impression, and a few surgeons are yet blinded with the plausible scheme of giving time for the collateral vessels to enlarge. I remember a patient who had been advised to let the operation be postponed on such a ground, though the swelling in the ham was already as large as an egg.

Mr. Guthrie is of opinion, that the collateral branches begin to enlarge shortly after the commencement of the disease, as a part of the curative process, which nature, in most instances, endeavours to set up; "the essential points of which are, in an extremity—1. The obliteration of the artery above and below the tumor. 2. The coagulation of the blood within it. 3. The enlargement of the collateral branches above and below it."

"It is necessary (he afterwards observes), that this enlargement of the collateral branches should take place, because in many cases, the artery beyond or below the tumor is obliterated long before any operation is performed. The main supply of blood is already cut off from the extremity, and the operation adds very little to the derangement of the circulation which has already taken place below the tumor."

These facts appear to Mr. Guthrie to prove, what, indeed, cannot be doubted, that the collateral circulation is not in the same stage of preparation, in a limb whose main artery has been divided, as in one where an aneurism has existed for some time. They also explain why mortification is more common after wounded arteries, than after operations for aneurism. (See *Guthrie, On Dis. of Arteries*, p. 139.)

In a case of wounded artery, I should say, that the greater tendency to mortification is likewise promoted by the following circumstances:—The common injection and distention of the cellular tissue with blood, the frequent simultaneous injuries of the collateral vessels and considerable veins, and sometimes of important nerves, the weakness often resulting from profuse external hemorrhage, and the depth and extent of the wound to various other textures.

Although Mr. Guthrie considers, that the doctrine of the power of the collateral vessels always to carry on the circulation in aneurism has been carried rather too far, and that the allowance of some little time for them to enlarge themselves for that purpose is useful; there may appear but a trivial difference between him and other surgeons, or, perhaps, none at all, when his belief is recollected, that such enlargement occurs in an early

stage of the disease, and his precept is remembered, "that an aneurism should never be allowed to attain that size, which may render it injurious to the surrounding parts. (Op. cit. p. 140.) As I believe, that the early editions of my surgical writings contain the first condemnation of the old plan of delaying the operation till the collateral vessels had had time to increase in size, this is a practical point in which I feel some interest; and the more I have seen and read of the present disease has only served to confirm the accuracy of the practical advice long ago delivered in my works on the advantages of early operations for aneurism.

The effects of the pressure of aneurisms upon the bones, are justly regarded as an unpleasant complication, when they take place in an extensive degree, and, according to some writers, they may sometimes induce a necessity for amputation. (*Boyer, Traité des Mal. Chir.* t. ii. p. 117.) However, I have never seen a case of this description; and Mr. Hodgson, as we have already explained, informs us, that the affection of the bones is hardly ever attended with exfoliations, or the formation of pus, so that if the aneurism can be cured, the bones will generally recover their healthy state, without undergoing those processes which take place in the cure of caries, or necrosis. (*On Diseases of Arteries and Veins*, p. 80.) At the same time, there can be no doubt, that where the tumor has been allowed to attain a large size, before an attempt is made to cure it, and where, from this cause, both the neighbouring soft parts and the bones have suffered considerably, the completion of a cure—that is to say, the full restoration of the use of the limb—must be far more distant than in other cases, where the cure is attempted in an earlier stage. Here, then, we see another reason against the pernicious doctrine of waiting for the enlargement of the anastomosing vessels, in addition to that which has been urged in the previous column.

The age, constitution, and state of the patient's health, are also to be considered in the prognosis; for they undoubtedly make a great difference in the chance of success after the operation.

The operation, however, should not be rejected on account of the age of the patient, if the circumstances of the case in other respects appear to demand it; for it has often succeeded at very advanced periods of life. "I have seen several aneurisms cured by the modern operation, in patients above sixty years of age." (*Hodgson* p. 304.) Similar cases have fallen under my own notice. In cases of popliteal aneurism, Sir Astley Cooper operated with success on one patient aged eighty-five, and on another sixty-nine years old, with the same favourable result.

When an aneurism exists in the course of the aorta, the violent action of the heart, excited by an operation in the extremities, may cause it to burst, and prove instantaneously fatal. Two cases occurred a few years ago in this metropolis, in which the patients died from such a cause during operations for popliteal aneurisms. (See *Hodgson, On Diseases of Arteries*, p. 306; *London Med. Rev.* vol. ii. p. 246; and *Burns, On Diseases of the Heart*, p. 228.) Were the co-existence of the internal aneurism known, the operation for the other tumor would be improper, and the surgeon should limit the treatment to palliative means.

Experience proves, however, that the circumstance of there being two aneurisms in the limbs should not prevent the operation, which is to be practised at separate periods. Facts, in support of this statement, are quoted by Mr. Hodgson. (P. 310.)

An aneurism may form spontaneously, and yet the person may recover after an operation, without having a recurrence of the disease in any part. Mr. Guthrie knew a man who survived the operation for popliteal aneurism in both limbs for twenty-five years, and died at last of fever. (*On the Diseases and Injuries of Arteries*, p. 61 and 121.)

OF THE SPONTANEOUS CURE, AND GENERAL TREATMENT, OF ANEURISMS.

The obliteration of the sac, in consequence of a deposition of lamellated coagulum in its cavity, as Mr. Hodgson has well described, is the mode by which the spontaneous cure of aneurism is in most instances effected. The blood soon deposits upon the inner surface of the sac a stratum of coagulum; and successive depositions of the fibrous part of the blood by degrees lessen the cavity of the tumor. At length the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery on both sides of the sac as far as the giving off of the next large branches. The circulation through the vessel is thus prevented; the blood is conveyed by collateral channels; and another process is instituted, whereby the bulk of the tumor is removed. (*On the Diseases of Arteries*, &c. p. 114.) Such desirable increase of the coagulated blood in the sac is indicated by the tumor becoming more solid, and its pulsation weak, or ceasing altogether. In aneurisms of the limbs, the cure by coagulation is believed by Mr. Guthrie to be promoted by two natural processes, viz. the enlargement of the collateral branches, and the effort made to close or shut up the lower openings from the aneurism. He states, that in the Hunterian collection, there are several examples of all the openings into the aneurism, save the upper one, having been closed during life. It does not appear to him, however, that the coagulation of the whole of the blood in an aneurismal tumor is the necessary consequence of the closure of the lower opening; and unless this happens, the swelling will continue to increase. (See *Guthrie, On Diseases of Arteries*, p. 90.)

Amongst Mr. Hodgson's plates may be seen one representing an aneurism of the femoral artery, or rather a dilatation of it, involving the whole of its circumference, and where the blood continued to pass through a narrow channel in the centre of the lamellated blood, nearly in its natural course. Had nature been allowed more time for the completion of her processes, what would have been the mode of cure? Probably the obstruction of the central channel by solid blood, the determination of the circulation to the collateral vessels, and then the gradual removal of the tumor by the absorbents. Whether a case, reported by Mr. Guthrie as one of an external aneurism cured with the artery remaining pervious, is an unequivocal example of this occurrence, I cannot undertake to determine. (See *Guthrie, On Diseases of the Arteries*, p. 100.)

Another mode, in which the disease is sponta-

neously cured, happens as follows:—An aneurism is sometimes deeply attacked with inflammation and gangrene; a dense, compact, bloody coagulum is formed within the vessel, shutting up its canal, and completely interrupting the course of the blood into the sac. Hence, the ensuing sphacelation, and the bursting of the integuments and aneurismal sac, are never accompanied by a fatal hemorrhage; and the patient is cured of the gangrene and aneurism, if he has strength sufficient to bear the derangement of the health necessarily attendant on so considerable an attack of inflammation and gangrene. I remember a femoral aneurism in the York Hospital, where a cure was accomplished in this manner. Mr. Guthrie has seen three cases of inguinal aneurism, attacked by inflammation and sloughing. (*On Diseases of Arteries*, p. 96.) One was the case under Mr. Albert, in the York Hospital, where the patient recovered; in the two others the patients died, worn out by the discharge and the extension of ulceration to the hip-joint; without which last complication, Mr. Guthrie deems it probable that both patients would have recovered—the ends of the artery, above and below the disease, having been obliterated.

When a patient dies of hemorrhage, after the mortification of an aneurism, it is because only a portion of the integuments and sac has sloughed, without the root of the aneurism, and especially the arterial trunk, being similarly affected. For cases illustrative of this statement, refer to *Hodgson, On Diseases of Arteries*, p. 103, &c.

All surgeons will concur with Mr. Guthrie, that the attempt at a cure by sphacelation is attended with so much peril, that, if possible, it should be prevented by a surgical operation. Yet "*the operation should never be had recourse to after mortification (that is to say, a deeply extending sphacelation) has begun.*" If the patient dies of the mortification, the operation is useless; and if he survives it, the operation is unnecessary." (See *Guthrie, On Dis. of Arteries*, p. 98.) When the inflammation and sloughing are superficial and very limited, the operation would be indicated, because, unless the arteries were first taken up, the patient would die of hemorrhage on the slough being loosened. Sir A. Cooper, however, tied the external iliac artery in two cases of inguinal aneurism when gangrene existed, and though the tumors burst, no hemorrhage ensued. The coagulum was discharged, the sac granulated, and the sores gradually healed. (See *Med. Chir. Trans.* vol. iv.)

A third way in which an aneurism may be spontaneously cured, is by the tumor compressing the artery above, so as to produce adhesion of its sides, and obliteration of its cavity. This mode of cure must be uncommon: it has been adverted to by Sir E. Home, Scarpa, Dr. John Thomson, and others; but some facts, tending to prove it, have been collected by Mr. Hodgson, and are published in his meritorious work. (See p. 107, &c.)

Rare as this mode of cure is, I do not coincide with Mr. Guthrie in looking upon this account as a mere theory (op. cit. p. 98); for we know by dissection, that the pressure of an aneurismal tumor upon the artery connected with it, may lead to the obliteration of the part or vessel pressed upon. Mr. Lawrence has mentioned in his lectures the particulars of a case, where the pressure of the sac of an aneurism in the groin,

upon the artery lower down, had rendered the artery in this situation impervious.

A fourth mode of cure is illustrated in a case, related by Sir Astley Cooper: a man, in Guy's Hospital, had an aneurism just below the groin. He was sitting before the fire, when he felt something burst in the upper part of his thigh. On examination, he found no blood had escaped, and, in fact, the aneurism had not yet reached the skin, so as to be adherent to it. His thigh, however, was enormously swelled; he was unable to use his limb, and was put to bed. For three days afterwards a pulsation was perceptible in the aneurism; but it then ceased, and the size of the limb began to diminish. At the end of four months, the aneurismal swelling had considerably subsided; he could use the limb; and in less than six months, he was discharged from the hospital. He afterwards fell a victim to the rupture of another aneurism in the abdomen. On examination of the body, it was found, that the aneurism in the thigh, just below Poupart's ligament, had burst under the fascia lata, and the femoral artery has been obliterated by the pressure of the large quantity of effused blood.

"The surgical treatment of aneurism (says Mr. Hodgson) consists in the obliteration of the cavity of the artery communicating with the sac, so that the ingress of the blood into the latter is either entirely prevented, or the stream which passes through it is supplied only by anastomosing branches, and consequently the force of the circulation is so much diminished, that the increase of the tumor is prevented, and the deposition of coagulum is promoted. By the absorption of its contents, and the gradual contraction of the sac, the cure is ultimately accomplished. The blood is conveyed to the parts, which it is destined to supply, by collateral vessels, some of which, being gradually enlarged, constitute permanent channels for the circulation. The obliteration of the artery is effected by the excitement of such a degree of inflammation in its coats, as shall produce adhesion of its sides. These objects have been attempted by the compression, or the ligature, of the artery." (P. 165.)

Such are the principles of the ordinary mode of cure; but it appears, from certain facts recorded by Mr. Wardrop, Dr. Bush, Dr. Mott, and other practitioners, that some aneurisms may be cured by a surgical operation, which was first suggested by Brasdor, or, according to Bichat, by Desault, and the design of which is to hinder the free transmission of blood through the aneurismal sac by tying the artery on that side of it which is most remote from the heart. This practice, however, is only allowable in certain examples, in which the application of a ligature in the common way is no longer practicable, because its success is much less probable, as might easily be anticipated, since the plan does not comprise the very desirable object of directly preventing the entrance of blood into the aneurismal sac. To this subject, however, we shall presently return.

According to Scarpa, *a complete cure of an aneurism cannot be effected, in whatever part of the body the tumor is situated, unless the artery, from which the aneurism is derived, be, by nature or art, obliterated, and converted into a perfectly solid, ligamentous substance, for a certain extent above and below the place of the ulceration, laceration, or wound.*

Notwithstanding aneurisms cannot in general be cured, as Scarpa has explained, unless the artery be rendered impervious for some extent above and below the tumor, I believe we must make an exception to this observation, with respect to the few aneurisms of the aorta (especially those of its arch), which, according to the records of surgery, have been diminished and cured by Valsalva's treatment. In such examples, we are not to suppose that the aorta becomes obliterated at its very beginning; but that the diminution of the quantity of circulating blood, the reduced impetus of this fluid, the lessened distention of the aneurismal sac, the general weakness induced in the constitution, and the increased activity of the lymphatic system, — all necessary effects of Valsalva's method, — have combined to bring about a partial subsidence of the tumor.

"It is a common opinion (says Mr. Hodgson), that the radical cure of an aneurism cannot take place without the obliteration of the artery from which the disease originates. It is probably owing to this idea, that aneurisms of the aorta have generally been considered as incurable diseases, and consequently that so little attention has been given to their treatment." (P. 118.) The facts, however, which this gentleman has related, satisfactorily prove — 1st, That a deposition of coagulum may take place in an aneurismal sac, to such an extent as entirely to block up the communication between its cavity and that of the artery from which it originates. 2ndly, That a sac, thus filled with coagulum, cannot prove fatal by rupture; and, 3rdly, That the gradual absorption of its contents, and the consequent contraction of the sac, may proceed to such an extent as to effect *the cure of the disease, without any obstruction taking place in the calibre of the vessel from which it originates.* (See cases 20, 21, 22, &c. *Hodgson, On Diseases of the Arteries, &c.* p. 119, &c.) In support of this doctrine, some facts are also cited from Corvisart. (*Essai sur les Maladies du Cœur*, p. 313, &c.)

A part of these cases, it is true, are not viewed exactly in this light by Kreysig, who argues (as I think without much probability), that they might have been only adipose swellings, connected with, or formed in, the parietes of the artery, — a disease described by Stenzel. (*German Transl. of Mr. Hodgson's book*, p. 174.)

Corvisart himself, instead of regarding such tumors as aneurisms *in the progress of cure*, conceived them to be aneurisms *in the course of formation*; and, on this point, Mr. Guthrie suspects that he was correct; because "the contents of the tumor were a substance of *less consistence than suet*, whilst in all the cases of spontaneous cure, in which, from the history, the previous existence of aneurism was known, the contents have always been *firm, or very firm.* (*Guthrie, On Dis. of Arteries*, p. 33.) But whatever may have been the nature of the swelling referred to by Corvisart, the fact of sacciform aneurisms of the aorta being sometimes entirely filled up by solid blood, and the disease cured on this principle, with the great channel of the aorta itself remaining pervious, is now universally acknowledged.

That a punctured artery may occasionally be healed, and still continue pervious, Scarpa himself proves, by a case which he examined, where an aneurism took place from the wound of a lancet in bleeding. In the article HEMORRHAGE, we

shall see that Jones's experiments show the same thing, and the particular circumstances in which it may happen. But the occurrence is rare, and Scarpa says that it can hardly be called a *radical* cure, as the cicatrix is always found in a state ready to burst and break, if the arm be, by any accident, violently stretched or struck where the wound was situated.

In the spontaneous cure of aneurisms, arising from arteries of inferior size to that of the aorta, repeated examinations have proved, that the deposition of coagulum does not merely fill up the sac, but obliterates the tube of the artery, above and below the disease to the next important ramifications. Yet, even here, exceptions probably take place; for Mr. Hodgson has brought forward one instance, in which a small sac, which originated from the anterior artery of the cerebrum, was completely filled with firm coagulum, which did not extend into the cavity of the vessel. (*On Diseases of Arteries*, p. 132.) And he reports the particulars of a *true* femoral aneurism, communicated to him by Sir A. Cooper, in which, after the patient's death, the femoral artery was found dilated into a sac, which was lined on all sides with very firm layers of coagulum, in the centre of which was an irregular canal, through which the circulation was continued. As the inside of this canal presented a membranous appearance, it was inferred that the aneurism had been cured. (*Op. cit.* p. 134.) Here I may be permitted to remark, that, if this case be correctly reported, viz. if it were a true aneurism by dilatation of all the arterial coats, and the inside of it was *every where* lined by firm layers of coagulum, it amounts to a proof that such a deposition is not entirely confined to aneurisms by rupture, as Scarpa supposes. And, in addition to this fact, I may mention, as referring to the same question, a case of aneurism from dilatation of the arterial coats, observed by Guattani, where the same process took place. "*Arteriæ iliacæ ovalem hanc partem aneurysmaticam polyposa substantia variæ densitatis adeò infarctam esse denotebam, ut tunicarum ejusdem forma penitus destructa in uniformem massam, spongiæ cerâ imbutæ similem, transformata videretur.*" (*Hist. xvii. Collect. Lauth.* p. 158.)

Whenever the ulcerated, lacerated, or wounded artery is accurately compressed against a hard body, like the bones, it ceases to pour blood into the surrounding cellular sheath, because its sides being kept in firm contact, for a certain extent above and below the breach of continuity, become united by the adhesive inflammation, and converted into a solid ligamentous cylinder. Molinelli, Guattani, and White give examples and plates illustrative of this fact. When aneurisms get well spontaneously, the same fact is observed after death, as Valsalva, Ford, &c. have demonstrated. I have myself seen, in St. Bartholomew's Hospital, an instance in which a man had had a spontaneous cure of an aneurism in the left axilla, but afterwards died of hemorrhage from another aneurismal swelling under the right clavicle: the artery on the left side was found completely impervious. Dr. Albert had under his care, in the York Hospital, Chelsea, a dragoon, who recovered spontaneously of a very large aneurism of the external iliac artery: the tumor sloughed, discharged about two quarts of coagulated blood, and then granulated, and finally healed up.

Paoli relates a similar termination of a popliteal aneurism, and Moinichen and Guattani give other examples. Hunter found the femoral artery quite impervious, and obliterated, at the place where a ligature had been applied fifteen months before. Boyer noticed the same fact in a subject, eight years after the operation. Petit describes the spontaneous cure of an aneurism at the bifurcation of the right carotid: the subject having afterwards died of apoplexy, the vessel, on dissection, was found closed up and obliterated from the bifurcation as far as the right subclavian artery. Desault had an opportunity of opening a patient, in whom a spontaneous cure of a popliteal aneurism was just beginning: he found a very hard, bloody thrombus, extending for three finger-breadths into the tube of the artery, above the sac, and so firm, that it resisted an injection, and made it pass into the collateral branches.

Both the spontaneous and surgical cures of aneurisms have generally two stages: in the first, the entrance of the blood into the aneurismal sac is interrupted; in the second the parietes of the artery approach each other, and, becoming agglutinated, the vessel is converted into a solid cylinder. This doctrine is corroborated by the tumor first losing its pulsation, and then gradually diminishing and disappearing.

In order that compression may make the opposite sides of an artery unite, and thus produce a radical cure of an aneurism, Scarpa says, the degree of pressure must be such as to place these opposite sides in firm and complete contact, and such as to excite the adhesive inflammation in the coats of the artery. The point of compression must also fall above the laceration or wound of the artery; for when it operates below, it hastens the enlargement of the tumor: and Scarpa adds, that, in practice, bandages which are expulsive and compressive, are more useful for making pressure than any tourniquets or instruments, many of which are contrived to operate, without retarding the return of blood through the veins.

In order that pressure may succeed, the coats of the vessel, at the place where it is made, must be sufficiently free from disease to be susceptible of the adhesive inflammation. When the arterial coats, round the root of the aneurism, are much diseased, Scarpa considers them as insusceptible of the adhesive inflammation, although compressed together in the most scientific manner, and even when tied with a ligature, which only acts by making circular pressure on the vessel.

Some advise trying compression in every case of aneurism, whether small, circumscribed, soft, flexible, indolent, or elevated, diffused, hard, and painful. But, in the latter case, Scarpa represents compression as decidedly hurtful. He says also, that every bandage which compresses the aneurism, and also circularly constricts the affected part, is always injurious. The bandage, likewise, which compresses only the aneurism, and directs the point of pressure below the rupture in the vessel; that which, on account of the great size, exquisite sensibility, depth of the root of the aneurism, and fleshy state of the surrounding parts, cannot effectually compress the artery against the bones, so as to bring the opposite sides of the vessel into contact; and, lastly, the compression applied to a spontaneous aneurism, attended with a steatomatous, ulcerated, earthy disease of the arterial coats;

—ought to be considered as more likely to do harm than benefit. In cases of a completely opposite description, bandages have produced, and may produce, a radical cure, and should not be entirely disused. (*Scarpa, On Aneurism*, ed. 2, p. 221.)

Guattani first employed compression systematically for the cure of aneurisms; and out of fourteen cases in which he adopted the plan, four were cured by it. Be it remarked, that this distinguished surgeon applied, first charpie and compresses over the tumor, and then a roller, with only moderate tightness, from the lower part of the swelling to the upper part of the limb. The bandage, which was kept wet with an astringent refrigerant lotion, was changed about once in three weeks. The patient was kept on a very low diet, perfectly quiet in bed, and a few general bleedings were practised. Mr. Freer details some other examples of success, and so does Lisfranc (*Op. cit.* p. 29); but, in general, pressure has hitherto been applied to the tumor itself,—a method less likely to answer than that of making pressure on a sound part of the artery. Mr. Freer recommends the employment of Sennio's instrument, or the following method:—First place a bandage, moderately tight, from one extremity of the limb to the other; then put a pad upon the artery, a few inches above the tumor; next, surrounding the limb with a tourniquet, let the screw be fixed upon the pad, having previously secured the whole limb from the action of the instrument by a piece of board, wider than the limb itself by which means the artery only will be compressed, when the screw is tightened. The tourniquet should now be twisted till the pulsation in the tumor ceases. In a few hours the limb will become œdematous and swelled, when the tourniquet may be removed, and the pressure of a pad and roller will afterwards be enough. In experiments which this gentleman made on the radial arteries of horses, these vessels were found to become inflamed, and to be rendered impervious, by such a process. (*Freer*, p. 112.) Dubois is stated to have cured an aneurism of the thigh by steady pressure on the vessel for twenty-four hours. (*Med. Chir. Trans.* vol. iv. p. 437.)

Sir A. Cooper describes another machine for compressing the femoral artery, in cases of popliteal aneurism: it was used by Sir W. Blizard.—"The points of support for this instrument, were the outer part of the knee and the great trochanter, a piece of steel passing from one to the other; and to the middle of this a semicircular piece of iron was fixed, which projected over the femoral artery, having a pad at its end, moved by a screw, by turning which the artery was readily compressed, and the pulsation in the aneurism stopped, without any interruption to the circulation in the smaller vessels." But although the patient on whom it was tried possessed unusual fortitude, he was incapable of supporting the pressure of the instrument longer than nine hours. (*Med. and Phys. Journal*, vol. viii.) Mr. White, of the Westminster Hospital, tried pressure, by means of a newly invented spring, supposed to possess peculiar advantages. "The woman bore the pain heroically for five days, but the parts compressed sloughed deeply. The cure was completed; but (says Mr. Guthrie), the pain, danger, and risk incurred, were infinitely greater than any which could have been sustained from the usual

operation." (*On Dis. of Arteries*, p. 142.) Few patients, indeed, can endure the pressure of such instruments a quarter of this time, when they are put on sufficiently tight to afford any chance of obliterating the artery; and, on account of the suffering which they produce, they are rarely used by modern surgeons.

THE TREATMENT OF ANEURISM BY COMPRESSION.

[In consequence of the dangers and difficulties attendant upon the use of the ligature, surgeons have for many years past endeavoured to treat aneurism by compression. The employment of direct pressure on the aneurism was almost naturally suggested as a means to counteract the extension of the disease by the pressure of the blood from within, and has, consequently, been applied from a very early period in the treatment of the affection. This plan of treatment was first employed by Bourdelot, at the close of the seventeenth century; afterwards by Genga, Heister, Guattani, and others. These surgeons made the pressure directly upon the sac; and Guattani and Flajani relate several cures that they effected in this way; but the method was so uncertain in its results, and so dangerous, from irritating and inflaming the sac, that it fell into disuse. The French surgeons introduced a modification of the pressure plan, by laying open the sac, clearing out its contents, and applying the pressure directly over the ends of the vessel. Deschamps exposed the artery leading to the sac, and compressed this with an instrument he termed the "presse artère." These barbarous modes of treatment, however, were entirely set aside by the facility and comparative success of the Hunterian operation, and compression in aneurism was rarely practised by surgeons after the great step made by John Hunter in the treatment of this disease. Yet we find that John Hunter himself, Blizard, and Freer attempted, though with but little success, to cure this disease by pressure on the artery leading to the sac. Pelletan and Dubois appear to have been the first who employed the pressure upon the artery above the sac, instead of upon the aneurism itself: this was in 1810. Since this period various attempts were made methodically to treat aneurisms in this way; but the merit of having introduced the practice of compression in the treatment of aneurism into modern surgery, of having given it a definite place in our art, and of having established the true principles on which it acts, incontestably belongs to the Dublin surgeons; amongst whom, the names of Hutton, Bellingham, Tufnell, and Carte deserve especial mention. In the early trials of the cure of aneurism by compressing the artery on the cardiac side of the tumor, the surgeons who employed this method acted on an erroneous theory, and the principle not being understood, the practice was bad. It was supposed that it was necessary for the cure to take place, that the *whole* flow of blood through the artery should be entirely arrested, that inflammation of the vessel at the point compressed should be set up, and that the consolidation of the aneurism depended upon the obstruction of the vessel consequent upon this inflammation. This led to compression being exercised so forcibly, with the view of exciting inflammation in the artery, that the patient could seldom bear it for a sufficient length of time to effect a cure, sloughing

of the skin commonly resulting as a necessary consequence of the severe pressure to which it was subjected. To the Dublin surgeons belongs the very great merit, not only of having pointed out the error of this doctrine, but of having distinctly laid down as the principle of the practice, that the aneurism was cured, when the artery leading to it was compressed, in precisely the same way as when a spontaneous cure takes place, or when the Hunterian operation is performed—viz. by the deposit of stratified fibrine in the sac, and by the consequent consolidation of this, aided by the contraction of the walls of the sac; and that, as in the case of the ligature of the vessel, it was not necessary for the whole of the circulation through the artery to be entirely and permanently arrested, but merely for it to be lessened in quantity and force to such an extent as to be compatible with the formation of laminated fibrine in the sac; and it was clearly shown by examination after death that if the pressure were properly conducted, the artery was in no way injured or occluded at the part compressed. This recognition of the true principles on which compression of the artery leading to the sac cures the aneurism, has led to important results; for, as the severe pressure that was formerly considered necessary is now known, not only to be useless, but to be absolutely injurious, no amount of compression is exercised beyond what is requisite to restrain and moderate the flow of blood into the sac; no attempt being ever made to compress the artery so severely as to lead to its obliteration by inflammation.

Though I have stated generally that aneurisms, when treated by compression, are cured by the deposit of laminated fibrine, I think this remark ought to be confined to the common sacculated form of the disease. In the tubular variety, which is certainly of far less frequent occurrence in the extremities, the cure of the aneurism takes place by contraction of the sac, and by its becoming filled by fibrine in a somewhat irregular manner. Illustrative of this mode of cure, there is a preparation in the Museum of University College.

The success of the treatment by compression depends greatly upon a scrupulous attention to a number of minor circumstances, which, though trivial in themselves, become of importance when taken as a whole. During the whole of the treatment, also, the patient's general health should be attended to, in accordance with those dietetic and medical principles that have already been laid down in speaking of the constitutional treatment of the disease, having for their object the increase of the fibrination of the blood. The irritability of the heart and arteries must also be subdued, and the irritation of the system lessened, by the use of opiates, and the patient should be put into a comfortable bed, with firm and well secured pillows and mattresses, so that his position be not changed. As it is principally in aneurism of the lower extremity that this plan of treatment can be employed, we shall proceed to describe the method of its application here; and, in doing so, I would remark, that much of the success of the treatment depends on a scrupulous attention to minute details.

The limb having been bandaged smoothly, with a soft or air pad upon the tumor, so as to approximate its sides, and laid comfortably on pillows, the thigh should be shaved, and dusted with hair-powder. The apparatus must next be applied,

and much of the success of the treatment will depend upon the kind of instrument used. The ordinary horse-shoe, or Signorini's tourniquet, was the one first employed, and this will, in many cases, answer the purpose perfectly well; but as it is somewhat difficult to regulate the pressure with this instrument, and as it is not unfrequently exercised too powerfully, it has generally given place, at the present day, to the very ingenious apparatus of Dr. Carte, which, as it substitutes an elastic force derived from vulcanised india-rubber bands for the unyielding pressure of the screw, accommodates itself better to the limb, and is less likely to produce injurious compression. This instrument, as well as the other contrivances which have at various times been invented for the treatment of aneurism by compression, are described by Drs. Bellingham and Tufnell, in their works on this subject, to which I must refer for a fuller account than I can here give. In some cases, the circulation through the artery may conveniently be controlled by the pressure of a weight laid over it in the groin as it passes over the pubes; usually from a four to a seven pound weight is sufficient for this purpose. In this way, when only one compressor is applied on the limb, the flow of blood may be checked during the time that the screw is loosened. Care must of course be taken that the weight do not slip off. It is best made of lead, cast in a conical shape, and may be retained *in situ* by having a wide leather socket made to fit it, shaped somewhat like the hopper of a mill; its broad end should be upwards, and the narrow end press on the vessel.

In applying the compressor, especial care must be taken that it is well padded in every part, so as not to gall the skin. In some of the early cases in which I saw compression employed in London by means of the horse-shoe tourniquet, much inconvenience resulted from want of attention to this particular. The tendency to fretting of the skin is much lessened by powdering the limb, and the removal of the cuticular hairs by shaving, diminishes materially the irritation produced by the instrument. In order to keep up continuous pressure, and, at the same time, to prevent any one part of the skin being injuriously galled, it is of very great consequence that two instruments should be used at the same time, so that when one is screwed up, the other should be loose; these instruments need not be placed closely together. If the aneurism be in the ham, it will be sufficient for one to be applied to the groin, whilst the other is put upon the middle of the thigh. In using the instrument, the great point, as Dr. Tufnell most properly remarks, is to control the circulation with the minimum of pressure; in order to do this, the first instrument should be screwed up so that all pulsation ceases in the tumor, but still not so tightly as to arrest all the flow of blood through it. As the pressure exercised by this becomes painful, it must be slightly loosened, and the second one screwed up. In this way an alternation of pressure can be kept up without much pain or inconvenience. If possible, the patient should be taught how to manage the instrument himself, and will often find an occupation and amusement in doing so. If, however, it excite much pain or irritation, as it does in some subjects, it may be necessary to give opiates. The pressure should, if possible, be continued during sleep, but if it pre-

vent the patient taking his natural rest, the suggestion made by Dr. Tufnell, of unscrewing the instrument slightly, and when the patient is asleep, gently tightening it again without awakening him, may advantageously be adopted; it is indeed surprising how very little unscrewing will relieve the pain of the compression. A large cradle should then be placed over the patient's body, so that the weight of the bed-clothes may be taken off the apparatus, and that the patient may manage it without risk of disturbance. Should there be still much uneasiness, the instrument might be taken off for a few hours, and compression kept up in an intermittent manner. Even under such circumstances as these consolidation of the sac may ensue.

The effects upon the tumor vary considerably. In some cases it rapidly and suddenly solidifies; more commonly, however, this is a gradual process, the aneurism becoming more painful and solid, with less pulsation and bruit. As the solidification takes place, there is usually a good deal of restlessness, a feeling of general uneasiness, and of constitutional disturbance, which is best quieted by opiates. As the pressure is continued, and the tumor begins to harden, the anastomosing vessels enlarge, with a good deal of burning pain in the limb generally, and arterial pulsations in situations where usually none are felt. The abnormal pulsation, in these cases, is always found to occur in much the same situations, the same vessels appearing to undergo dilatation. Thus Tufnell has made a remark, which I have had more than one opportunity of verifying, that in the treatment of popliteal aneurism by compression, three arteries will be found to be enlarged, one of which passes over the centre of the tumor, another over the head of the fibula, and the third along the inner edge of the patella; he also states that the severe burning pain which is felt in these cases, is owing to the artery accompanying the communicans peronei nerve being enlarged. After complete solidification of the tumor has taken place, the compression ought to be continued for at least forty-eight hours, so as to secure against the occurrence of a relapse.

The duration of the treatment varies very greatly. In some cases the tumor has become solidified in a few hours or days. In other instances again the treatment must be protracted for more than three months before a cure resulted. Of twenty-six cases of femoral or popliteal aneurism cured by compression, in the London Hospitals, the average time, according to Mr. Hutchinson, was nineteen days. Much of course will depend, in this respect, on the constitution of the patient, and on the condition of the tumor; those circumstances which are most favourable to the spontaneous cure of the aneurism will also influence the rapidity of the cure by compression.

Of the great value of compression in the treatment of aneurism there can be no doubt; but yet it cannot be looked upon as taking the place of the ligature in the cure of this disease, except in those cases in which the tumor is situated in the arteries of the lower extremity, below the middle of the thigh. In aneurisms occurring in the vicinity of the trunk, as in the iliac, the carotid, subclavian, and axillary arteries, it is quite inapplicable. Spontaneous aneurism being extremely rare in the upper extremity, and as the traumatic forms of the disease which occur here, generally require that

the sac should be laid open, it is seldom found necessary to have recourse to it in this part of the body, though it may be, and has been, successfully applied to the brachial artery.

The great question with regard to compression appears to me, after all, to be whether it possesses any special advantages over the ligature, in the treatment of femoral and popliteal aneurisms to which its employment is necessarily chiefly confined. The principal objections that have been urged against compression are that its employment is more painful and tedious than the use of the ligature, and that those cases that are unpromising to the ligature, or that require amputation rather than it, are equally unfavourable to compression, and cannot be saved by the employment of this means.

To these objections I think it may with justice be answered, that the pain attendant on the employment of compression depends very greatly upon the skill and care with which the apparatus is applied and managed throughout, and that much depends upon the kind of instrument that is used, being certainly much diminished when Carte's elastic instrument is employed. With regard to the relative tediousness of the treatment under the two plans, it would appear that in reality there is but little difference; for although some cases in which compression is used, are prolonged over a considerable space of time, yet they do not occupy more than is often consumed when accidents of various kinds follow the use of the ligature; and it not unfrequently happens in compression, what can never occur after the employment of the ligature, that the patient is cured of his disease in a few hours or days. Taking, however, the average of the Dublin cases, we shall find that the treatment lasted twenty-five days, and in the recent London cases but nineteen, and this is not very different from what happens with the ligature; for of fifty-four cases recorded by Crisp, in which the femoral artery was tied, the average time for the separation of the ligature was eighteen days, and if to this a week more be added for the closure of the wound, and for the treatment of the various accidents so often accompanying and following the ligature, we should probably be within the mark, and yet only bring the duration of the treatment of the two methods to the same level.

After all, surgeons will eventually be guided in their estimate of the value of the two plans of treatment, not so much by the question of submitting their patients to a slightly more painful or tedious treatment, as to the comparative risk of life attendant upon one or other method. Upon this point the statistics have yet to be made; partly because the cases of the treatment of aneurism by compression have not as yet been very numerous, and partly because the unsuccessful cases of ligature have not been so commonly published as the successful ones. If, however, we compare the 32 cases of femoral and popliteal aneurism treated in Dublin up to February, 1851, as given by Dr. Bellingham (*Med. Chir. Trans.* vol. 34), with the results of the 188 cases of femoral and popliteal aneurism, recorded by Norris, in which the artery was ligatured, we shall find, that of the 32 compression cases 26 were cured; in 1, the ligature was applied after pressure had failed; in 2, amputation was performed; in 1, death occurred from erysipelas; in 1, from chest disease; and in 1 case

the pressure was discontinued. Thus it would appear, that 6 out of the 32 failed, being in the proportion of 1 to 5·3 cases, and 2 died, being in the ratio of 1 to 16. Of the 188 cases in which the artery was ligatured, 142 were cured, 46 died, 6 were amputated, in 10 the sac suppurated, and in 2 gangrene of the foot occurred. Thus the deaths after ligature were in the proportion of 1 to 4, and the failures or serious accidents, of 1 to 3, showing clearly a very considerable preponderance in favour of the treatment by compression. Besides which, in many patients who recovered after the ligature, various accidents, such as gangrene, erysipelas, secondary hemorrhage, &c., resulted as the direct consequences of the treatment, and these do not happen when pressure is employed.

If the compression fails, the ligature may then often be advantageously applied; and as has been shown by the known cases, with a better success than if compression had not previously been tried, that treatment having caused the collateral circulation to enlarge, and thus lessened the tendency to gangrene.

It should also not be forgotten that in some cases, such as when aneurism is complicated with heart disease, or occurs in a very broken and unhealthy constitution, in which the operation necessary for the application of the ligature would scarcely, or not at all, be admissible, compression may be safely employed.

After carefully considering the relative merits of the two plans of treatment, I think we may conclude that, though in some few cases neither method can be adopted, and amputation is the sole resource, yet, that in others compression can be employed when it would not be safe to have recourse to the use of the ligature; and that in all ordinary cases of femoral and popliteal aneurism especially, compression should be preferred to the ligature, inasmuch as it is not a more tedious, and an infinitely safer method of cure. At the same time it must not be forgotten that its success depends very greatly on the continuous care bestowed upon the case during the progress of the treatment.]

MANIPULATION, GALVANO-PUNCTURE, AND PERCHLORIDE OF IRON.

[Mr. Fergusson has proposed to treat some aneurisms by a procedure which he terms "manipulation." This consists in squeezing the aneurismal tumor in such a way as to detach a portion of the coagulum within it, which, being carried on with the current of blood into the distal end of the artery, obstructs this; and thus, by impeding the circulation through the sac, may lead to the gradual consolidation of the tumor. This procedure has as yet been employed to too limited an extent to enable us to form an estimate of its value, and can scarcely be considered, nor is it intended to be of very general application. To such aneurisms, however, that are not amenable to ordinary surgical treatment, as those situated at the root of the neck, more particularly of the subclavian artery, it might possibly be advantageously applied. It is scarcely necessary, however, to point out the obvious danger of rupture of the sac, or of the diffusion of the aneurism on the separation of the coagulum, to make surgeons adopt due caution in carrying out this method of treatment.

The attempt to procure consolidation of an aneu-

rismal sac by the employment of electricity or galvanism is of comparatively recent date. It appears to have been first practised by Mr. B. Phillips, about the year 1832. Little attention, however, was given to this mode of treatment until a few years back, when it was revived by some of the French and Italian surgeons, especially by Petrequin and Burci. The principle on which this operation is conducted consists in endeavouring to produce coagulation in the aneurismal sac, by decomposing the blood contained in it, by means of the galvanic current. In some instances, the attempt to do this has induced, and, in all, it must occasion the liability to inflammation of the sac and of the surrounding structures; as the change that is sought to be effected in the contained blood, consists not in the deposit of its fibrine, but in the coagulation of it *en masse*. It has of late been recommended to conjoin the employment of compression of the artery, either above or below the sac, with the transmission of the galvanic current through it, there being in this way less liability for the coagulum that is deposited to be broken down and washed away, as would happen if the current of blood were allowed to pass through the sac whilst it is in the act of forming.

The coagulation of the blood is effected by introducing two acupuncture needles into the sac in opposite directions, and keeping them in contact with one another, after connecting them with a galvanic battery of moderate tension, when coagulum becomes deposited around one of the needles. The operation should be continued for periods varying from ten minutes to a quarter of an hour, and requires to be repeated several times. Petrequin recommends that the direction of the current be changed from time to time, so that a number of clots may be formed in the sac. In this way a soft mass of coagulum may occasionally be formed in the tumor, so as to fill it up more or less completely, and to prevent the passage of blood through it. Occasionally it happens, however, that the blood has continued fluid, and the sac pervious, no coagulation having been effected; and in other instances, again, the amount of inflammation that has been set up in the sac has been so great as to give rise to its sloughing, to the occurrence of secondary hemorrhage from it, and to the loss of the patient's limb or life. This inflammation may, in some cases, doubtless, have been the result of the injury inflicted upon the sac by the introduction of the needles, and by the charring of the tissues by them; but, in other cases, I think it probable that it may have taken place from the rapid coagulation of the contained blood, an occurrence that we have already seen tends especially to inflammation, suppuration, and sloughing of the aneurismal sac. The pain of the operation is always very considerable, so much so, that patients who have been subjected to it once have refused to submit to a repetition of it.

Up to July, 1851, M. Bonnet had collected 23 cases of aneurism treated in this way; of these, 8 were of the brachial artery, 7 of the popliteal, 2 of the subclavian, and 1 of each of the following: the ophthalmic, the temporal, the carotid, the thoracic aorta, the ulnar, and one unknown. Of these the proceedings failed in 13 instances; 9 cases were reported as successful, but in 7 of these, M. Bonnet states that doubts must be entertained both as to the results and as to the treat-

ment, for the cure took place not by galvano-puncture alone, but in some by the conjoined influence of compression and the application of ice; and in others, as the result of inflammation and suppuration of the sac. There are, consequently, only two cases in which the cure can clearly be attributable to this means alone, and without the occurrence of any serious accident.

When we compare the galvano-puncture with ligature or compression, in the treatment of external aneurism, it is, I think, impossible to hesitate for a moment in giving a decided preference to the latter modes of treatment. Not only is the principle on which it is attempted to procure obliteration of the sac in galvano-puncture a vicious and peculiarly dangerous one, viz. by the coagulation of the blood, and the inflammation of the wall of the sac; but the results that have hitherto been obtained by this method are not such as would justify a prudent surgeon in submitting his patient to experiments of this kind, when he possesses so certain and comparatively safe a mode of cure as that by deligation or compression. In *internal* aneurisms, or in those cases in which the disease is so situated at the root of the neck, that the artery can neither be ligatured with safety or compressed, galvano-puncture may perhaps be employed with some advantage, in conjunction with proper medical treatment.

The injection of aneurismal sacs with a solution of the perchloride of iron has also of late been practised, with the view of coagulating their contents, but such treatment is not only coarse and unscientific, but dangerous; and when compared with the ligature or compression of the artery leading to the sac, must be looked upon as a retrograde step in surgery.]

Lisfranc is acquainted with several cases in which ice was tried, either alone, or in combination with general means and compression. The successes were nearly equal to the failures; so that, according to Lisfranc, experience ascribes a good deal of efficacy to this treatment. He refers, however, to some recent investigations made by M. Moulinié, principal surgeon of the Hôpital St. André, at Bordeaux, which give a very different view of the subject. (See *Lisfranc, Des diverses Méthodes pour l'Oblitération des Artères*, p. 25.) The latter surgeon is, on the whole, rather in favour of the practice: he observes, that in all the examples in the Bordeaux Hospital, the application of ice was not aided by other means; and that it was tried without discrimination. When an aneurism is free from pain, and is neither inflamed nor too large, he thinks that the plan can hardly produce any dangerous effects. In order not to occasion sloughing, he advises the use of ice to be suspended every two or three hours or oftener. When the swelling is large, the parts very tense, their texture changed, and the skin thin, the practice is likely to accelerate the formation of a slough; and Breschet confirms a remark made by Mr. Hodgson, that some patients cannot continue this treatment beyond a few minutes, while others find it absolutely insupportable. (*Fr. Transl. of Mr. Hodgson's Work* t. i. p. 212—229.)

After all, the means, most to be depended upon, for curing aneurisms, is tying the artery above the tumor. This more certainly prevents the great ingress of blood into the sac, and, what is quite as important, more certainly excites adhesive inflam-

mation within the tied part of the vessel, and, by holding the opposite sides of it steadily in contact, brings about their union and an obliteration of the tube of the vessel with tolerable regularity. The chief current of blood into the sac is thus stopped, the contents of the aneurism are afterwards gradually absorbed, and the tumor dwindles away in proportion. The natural course of the blood being now permanently interrupted in the arterial trunk, it passes more copiously into the collateral branches; and these enlarging and anastomosing with others, which originate from the large arteries beyond the obstruction, the necessary circulation is carried on. (See ANASTOMOSIS.)

According to Scarpa, the circumstances chiefly preventive of success, especially in the popliteal and femoral aneurisms, are the following: rigidity, atony, or disorganisation of the principal anastomoses, between the superior and inferior arteries of the ham and leg; sometimes depending on advanced age, or on it, *together with the large size of the aneurism, which, by long-continued pressure, has caused a great change in the neighbouring parts*; or sometimes on steatomatous, ulcerated, earthy, cartilaginous disorganisation of the proper coats of the artery, not confined to the seat of the rupture, but extending a great way above and below the aneurism, and also to the principal articular arteries, and, occasionally, to portions of the whole track of the superficial femoral artery. In such circumstances, the ligature is apt to fail in closing the trunk of the artery; and, if it should succeed, the state of the anastomosing vessels will not admit of a sufficient quantity of blood being conveyed into the lower part of the limb. Hence, when the patient is much advanced in life, languid, and sickly; when the internal coat of the artery is rigid, and incapable of being united by a ligature; when the aneurism is of long standing, and considerable size, with caries of the os femoris, or tibia; when the leg is weak and cold, much swelled, heavy, and œdematous;—Scarpa considers the operation contra-indicated. I must, however, declare in this place, that I have seen large aneurisms as well as aneurisms in persons of advanced age, cured by the Hunterian plan; and, with respect to the affection of the bones, though it may be an unfavourable circumstance, its consequences are generally less serious than those of ordinary caries.

In the articles HEMORRHAGE and LIGATURE, I have described the effects of the ligature upon a tied artery, and particularly the various processes which arise from its application, and terminate in the permanent obliteration of the vessel. There, I have explained what are the best ligatures for use, as well as the safest manner of applying them. Confining myself at present to what expressly relates to aneurism, I shall merely annex the following general directions:—

First, The cord should be thin and round, such a ligature being most likely to effect a clean division of the internal and middle coats of the vessel, and not liable to produce extensive ulceration or sloughing. Lisfranc and others, who apprehend that a very thin silk ligature may make its way too rapidly through the external coat, prefer a strong round thread, or several united together, the flattened form being avoided. (*Lisfranc*, op. cit. p. 52.)

Secondly, The ligature should be tight, in order to insure the complete division of the internal and

middle coats, and to prevent its detachment; it being almost impossible, even with the thinnest ligature, entirely to cut through a healthy artery.

Thirdly, The vessel should be detached from its connections only to such an extent as is necessary for the passage of the ligature underneath it.

Fourthly, The immediate adhesion of the wound should be promoted by all such means, as are known to promote that process in general. (See *Hodgson, On Dis. of Arteries*, p. 225, 226.)

Fifthly, The ligature should be applied, if possible, to a sound portion of the artery. When the artery is affected with atheromatous or calcareous depositions at the part where some method must be tried for its obliteration, M. Lisfranc rejects the ligature and prefers compressing, or plugging the vessel, or, at all events, some means which will not occasion so much risk as the ligature of rapidly dividing the artery. (*De l'Oblitération des Artères*, p. 64.) If we were compelled to tie a diseased portion of artery, the chance of secondary hemorrhage, I believe, would not be lessened by following M. Lisfranc's advice. It is right to state, however, that the plan of plugging an ossified artery was sometimes adopted by Baron Dupuytren and M. Roux, though probably not in cases of aneurism. According to M. Manec, they used as a plug a piece of bougie, and then applied a common ligature.

Sixthly, it should not be placed too near a collateral branch, which would prevent the formation of the internal clot, and the process of obliteration of the vessel would be likely to be interfered with.

In the course of his experiments upon brutes, to ascertain the operation of the ligature, Dr. Jones arrived at a fact, which offered the probability of leading to an improvement in the operation for aneurism. (*Treatise on Hemorrhage*, chap. iii.) When a small firm ligature is applied to an artery, it causes the division of the internal and middle coats; and if it be afterwards removed, an effusion of lymph takes place between the cut surfaces into the cavity of the vessel. *If several divisions of the internal and middle coats be thus effected in the vicinity of each other*, the effusion of lymph was found by Dr. Jones to be sufficiently extensive to obliterate the cavity of the vessel. Dr. Jones mentions *several divisions* as necessary; an important fact, which has generally been overlooked, and the application of one ligature supposed to be all that was specified. Indeed, several divisions of the inner coat constitute in reality the process introduced by M. Amussat, and termed by him *Des Mâchures*. In the year 1800, Mr. A. C. Hutchison tied the brachial arteries of two dogs, and removed the ligatures immediately after their application: in both instances, as he assures us, the complete obliteration of the canal of the artery was the consequence of the operation. (See *Pract. Obs. in Surgery*, p. 103.) If, immediately after the operation for aneurism, the ligature could be removed, and yet the vessel became obliterated, it would be highly advantageous, as there would then be left in the wound no extraneous substance to prevent its union, or promote secondary hemorrhage, by extending the sloughing, or ulcerative process too far. It is to be regretted, that the repetition of the experiment by others has not been attended with success. Mr. Hodgson tried it, but the artery did not become impervious. (See *Experiments A. and B.*, p. 228, 229, of this gentle-

man's work.) Mr. Dalrymple, of Norwich, made the experiment not less than seven times on horses, and three times on sheep, and failed, in every instance, to obtain the same result as Dr. Jones. Not only was no coagulum formed, but even when the animal had been suffered to live until the thirteenth, fifteenth, and eighteenth days after the operation, the canal of the artery was not found obliterated. In each case, indeed, its calibre was contracted; but it was still capable of transmitting a lessened column of blood. (*Travers in Med. Chir. Trans.* vol. iv. p. 442.) Thus it appears that an effusion of lymph is an invariable consequence of the operation, and, as Mr. Travers has observed, the want of union is therefore owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion. The presence of the ligature, in the common mode of its application, effects this object; and for the success of Dr. Jones's experiments it appeared only necessary that the opposite sides of the wounded vessel should be retained in contact until their adhesion was sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure, as would retain the opposite sides of an artery in contact at the bottom of a recent wound, are too great to permit its employment. It occurred to Mr. Travers, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to insure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger, produced by the residence of a ligature upon an artery, arises from the irritation, which, as a foreign body, it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application of a ligature; whilst it is an ascertained fact, that lymph is in a favourable state for organisation in less than six hours, in a wound the sides of which are preserved in contact. (*Jones*, chap. iv. exp. 1.) If it be sufficient, therefore, to insure their adhesion, that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may in a great degree be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained, that if a ligature were kept six, two, or even one hour upon the carotid artery of a horse, and then removed, the adhesion was sufficiently advanced to effect the permanent obliteration of the canal. It appeared probable, that the same result would be obtained upon the healthy artery of a human subject. (See *Travers's Obs. in Med. Chir. Trans.* vol. iv. : and *Hodgson, On the Diseases of Arteries and Veins*, p. 228 et seq.)

Sir Astley Cooper performed one operation for a popliteal aneurism, with the view of ascertaining the efficacy of such a method on the human subject. He completely stopped the flow of blood for thirty-two hours, and then removed the ligature; but the pulsations of the tumor commenced again. He next applied the ligature forty hours longer, at the end of which time no pulsation recurred on the ligature being taken away. On the

twelfth day, however, a considerable bleeding took place, and it was necessary to take up the vessel anew.

Mr. A. C. Hutchison tried this method, as modified by Mr. Travers, in an operation, which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery. The ligatures were tied with loops, or slip knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumor, was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed, without the slightest disturbance of the vessel. In less than half a minute afterwards, the artery became distended with blood, and the pulsations in the tumor were as strong as they had been before the operation. Mr. Hutchison then applied two fresh ligatures; hemorrhage afterwards came on; amputation was performed, and the patient died. (See *Practical Obs. in Surgery*, p. 102, &c.) Now, as Mr. Hutchison chose to apply other ligatures, on finding that the pulsation returned, the above case only proves that the artery is not obliterated in about six hours, and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hemorrhage which occurred, I think it might have been expected, considering the disturbance and irritation which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas, only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures which were employed; an essential piece of information in forming a judgment of the merits of the preceding method. The application, removal, and reapplication of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones; and have, in more instances than that recorded by my friend Mr. Hutchison, brought on ulceration of the artery, and hemorrhage.

The limits of this work, prevent me from entering into the particulars of the interesting experiments, undertaken by Mr. Travers, upon the arteries of animals, for the purpose of ascertaining the earliest period when a ligature might be removed from an artery, without any risk of the vessel not being duly obliterated. A full detail of them may be seen in another work (See *Med. Chir. Trans.* vol. iv. and vi.); and others, in relation to the same question, may likewise be perused in Scarpa's appendix to his great work on aneurism. (*Memoria sulla Legatura delle principali Arterie degli Arti*, &c. fol. Pavia, 1817.) The cases above related, and other considerations, long ago satisfied me, that, flattering as the suggestion of Dr. Jones was, the plan of removing the ligature, previously to its natural separation, would never answer in the operation for the cure of aneurism, unless either an obliteration of the arterial tube would follow with reasonable certainty the taking away of the ligature directly after it had been applied and it had divided the inner coats of the vessel; or, at all

events, unless the ligature could be withdrawn at a determinate period, when either the same obliteration would surely ensue, or be already complete; and all this, with such regularity and infallibility in every case, that the surgeon would have no chance of being called upon to apply another ligature, do a second operation, or disturb the artery in any kind of way whatsoever.

At length, in the prosecution of this inquiry, in which Mr. Travers evinced a full determination to be guided by no motive but the love of truth, he tried the temporary application of the ligature in a case of brachial aneurism, which was operated upon Feb. 14, 1817. The artery was tied an inch and a half above the bend of the elbow with a noose ligature. The pulsation in the radial artery immediately ceased. On the 16th, at four o'clock in the afternoon, the ligature was removed with little difficulty, after having remained on the artery *fifty hours*. No pulsation ensued in the vessel below the point, where the ligature had been applied, and the case was completely successful.

On the 28th November, 1817, in a case of popliteal aneurism, Mr. Travers tied the femoral artery at one o'clock. On the 29th, at four in the afternoon, the ligature was removed without difficulty, after having been on the vessel *twenty-seven hours*. At this period no pulsation could be felt in the sac; but, at seven in the evening, a faint pulsation was perceptible. On the 30th, the pulsation, though very distinct, was less strong than before the operation. On the 2nd, 3rd, and 6th of December, the pulsation is described as still continuing. On the latter day, pressure was applied, by means of a roller, from below the knee to the groin, and was continued for a month, during which time the pulsation in the sac evidently became more feeble. On the 10th of January, the tumor became tense, and severely painful, and no pulsation in it could be distinguished. The next day, the swelling was more diffused and less prominent; and on the 12th, as the disease underwent no amendment, Mr. Travers tied the artery again, about two inches above the place where the former ligature had been applied. The next day the pain had diminished. The ligature was afterwards allowed to separate of itself; and the case went on favourably to the cure. According to Mr. Travers, the first of these cases tends to prove, that *the continuance of the ligature upon the artery for a period of fifty hours*, as certainly and completely answers the purpose of its application as if allowed to remain until thrown off by the natural process.

In the second case, Mr. Travers infers from the suspension of pain, and the diminished strength of the pulsation, for a month after the application of the temporary ligature, that a degree of impediment to the current of blood in the artery had been produced; circumstances, which once led him to entertain hopes, that the cure of the aneurism was gradually accomplishing. At length, however, the increase of the tumor, and the aggravation of pain, and inflammatory symptoms, dispelled such expectation, and it was thought necessary to tie the femoral artery a second time, and adopt the common mode.

There are one or two points about this case on which the author does not particularly dwell though they require consideration, ere one can form a correct judgment of the accuracy of one

of his positions, "that non-pulsation of the sac is a sign auspicious, or otherwise, simply as it stands connected with increase or diminution of bulk, and pain." (*Med. Chir. Trans.* vol. ix. p. 415.) The first question is, how are we to account for the sudden accession of pain, the absence of pulsation, the increase of the swelling, and the other changes which happened on the 10th of January? Judging from the particulars given, I should say, that at this period, the aneurismal sac gave way, and the disease changed from the circumscribed into the diffused form; an alteration which would account for the pulsation being entirely lost, the increase of pain, and the extension of the swelling, &c. Now, although the circumstance of the sac giving way, or the increase of pain, swelling, &c. on the 10th of January, may be taken as an argument, that the application of the ligature for *twenty-seven hours*, had failed in producing obstruction enough in the vessel to retard the progress of the disease, we ought to remember, that at the time when these changes happened, a trial of pressure was making, to which one might impute the change of the aneurism from the circumscribed to the diffused form, with quite as much probability, as to the enlargement of the sac by blood sent into it through the imperfectly obliterated artery. However this may be, certain it is, that the second operation was done, when no pulsation existed in the swelling; and, perhaps, therefore, the case would have been doubly interesting, had the artery not been tied a second time, until circumstances had unequivocally proved, that this cessation of pulsation, attended as it was with an inflammatory state of the tumor, would not ultimately have ended in the cure of the disease.

Here, however, I may be speaking rather in the spirit of an experimenter, whose curiosity has not been fully satisfied, than as a surgeon, who should always be governed by the paramount consideration of extricating his patient from danger; and this will appear the more likely, when I add, that my mind has long been made up about the inexpediency of the temporary ligature, as an innovation in surgery. The last case induced Mr. Travers to relinquish the temporary ligature; and, amongst other reflections, which inclined him to give up the practice, he candidly states, "that the adhesive union is prevented by the enclosure of a foreign body in the wound, long before suppuration has commenced. Suppuration is as certain to take place, though the ligature be removed after a few hours, as if it were left to be cast off; and the granulating process is more languidly performed, after an interruption, in its early stage, for the purpose of removing the obstacle to union, than where no such interruption has been given, and the obstacle has been removed by nature's own means. Hence, it follows, that the theory, which, in removing the ligature within a given time, proposed the double advantage of a quicker, as well as a surer process, fails in both points, when brought to the test of practice upon the human subject." (See *Med. Chir. Trans.* vol. ix. p. 416, 417.)

We have seen, that when a temporary ligature, which had been applied to the brachial artery *fifty hours*, was withdrawn by Mr. Travers, pulsation in the aneurismal tumor at the bend of the elbow did not return, and the disease

was cured; but that, in another instance, where the ligature had been allowed to remain on the femoral artery only *twenty-seven hours*, a feeble pulsation was renewed a few hours afterwards in a popliteal aneurism, and as the swelling became painful and more diffused, some weeks after this experiment, though no pulsation could then be perceived, the femoral artery was tied a second time, and the ligature left to separate in the usual manner.

But, from a case more recently published, it would seem, that the employment of a temporary ligature for only *twenty-four hours* on the femoral artery, may obliterate the vessel, and accomplish the cure of a popliteal aneurism. The patient was a sea-faring man, aged thirty-two; and the operator, Mr. Roberts of Carnarvon; Mr. Evans and Mr. Carrey, other surgeons of that town, being present at the application, and also at the removal of the ligature. No pulsation recurred in the tumor; the edges of the wound were brought together with adhesive plaster; and in eleven days the part was quite healed. (*Med. Chir. Trans.* vol. xi. p. 100.) This is the strongest case, I believe, which has been adduced in support of the use of the temporary ligature, whether we consider the short time for which it was applied, the permanent cessation of all pulsation, the quickness with which the wound healed, or the complete recovery of the use of the limb; for when the patient was met six months after the operation, "he could go to the mast-head with as great facility as at any period of his life." This fact proves, also, that there is a degree of irregularity in the period when the temporary ligature may be removed, without the pulsation in the tumor below the constricted part ever returning. Whether the variety is to be referred to temperament, the kind of ligature used, its greater tightness in one case than another, or other circumstances, is not at present determined.

The greatest advocate, which this practice has gained, is Scarpa, whose sentiments, however, about the most advantageous form of ligatures, and mode of applying them in cases of aneurism, are at variance with what is inculcated by the best and most experienced surgeons in this country. Instead of using a fine ligature, composed of a single piece of thread, twine, or silk, he employs a cord consisting of from four to six threads, according to the size of the artery which is to be tied; and, instead of aiming expressly at the division of the internal coats of the vessel with his ligature, as the generality of English surgeons do, for reasons explained in another part of this work (see HEMORRHAGE), he prefers a largish ligature, and interposes, between the artery and the knot, a small cylinder of linen spread with ointment, with the view of preventing the inner coats of the vessel from being divided. His reasons for this practice may be explained in a few words: he admits, that whenever there is a concurrence of all the circumstances, capable of inducing, in the tied artery, the proper degree of adhesive inflammation, above and below the place where a single circular ligature has been applied, this method is adequate to produce a speedy and steady closure of the arterial tube. But, says he, it sometimes happens, at least in man, that the pressure made by the circular ligature produces the ulcerative process more quickly in the artery, than the adhesive inflammation. In fact, the cir-

cular ligature ulcerates the artery in general about the third day after the operation; and the adhesive inflammation does not always complete its course in this period of time. During this delay of the adhesive inflammation, the ulcerative process, occasioned by the pressure of the ligature, attacks more quickly even than surgeons generally suppose, the external cellular sheath of the artery, and penetrates into the cavity of the yet pervious vessel; and this, of course, with increased quickness, when the inner coats of the artery are already divided by the ligature. The dangers of non-adhesion and too rapid ulceration of the artery, Scarpa thinks, are placed at the greatest distance by preserving undivided all the three coats of the vessel under the pressure of the ligature; and hence his partiality to larger ligatures than are now used by the best surgeons in England, and to the interposition of a cylinder of linen between the knot and the vessel, as recommended by Paré, Heister, and Platner. If, however, he has had reason to suspect that a simple circular ligature has frequently failed in England, because other innovations have been occasionally substituted for it, and because *we should not have sought for a better, if we had already had the best*, how much more vulnerable is his own practice on a similar principle; since, generally speaking, it has not retained half so many approvers as they who still express their preference to other methods, and more especially to the use of a single ligature, uncomplicated with other extraneous substances! Is it probable, he asks, that the single circular ligature, which was formerly used with doubtful success by the greatest surgeons, should now have become, as is pretended, the most certain means of preventing secondary hemorrhage? "It is now wished (says he) to ascribe the failures of Mr. Hunter, and of many other operators, not to the circular ligature, but to the improper treatment of the wound in general, and in particular to the introduction into it of lint, and, more especially, to the irritation occasioned by the ligature of reserve." On the contrary, it is argued by Scarpa, that, though Mr. Hunter, after his first trial, simplified the local treatment, though all skilful surgeons merely covered the wound with a pledget of soft ointment, and most of them omitted the reserve-ligature, yet, notwithstanding these reforms, secondary hemorrhage, after the use of a simple circular ligature, was not rendered less frequent. (*On Aneurism* p. 23, ed. 2.) With respect to the latter general assertion, its incorrectness may be learned by reference to the details of Mr. Hunter's own operations, and by going into the principal hospitals of this metropolis, where the use of a simple circular ligature for the cure of aneurisms rarely fails, so far as secondary hemorrhage is concerned. Why then did the operation more frequently fail here in former times? The answer is plain: the kind of ligature now employed in England cannot be compared to what was used in Mr. Hunter's time, or even to what was here in fashion forty years ago. And, besides the universal rejection of ligatures of reserve, practitioners now have a more thorough comprehension of what ought to be avoided in the operation, have a just fear of separating and disturbing the artery too much, know how to appreciate the advantage of closing the wound, and attach due importance to

the choice of smaller or more eligible ligatures. (See HEMORRHAGE and LIGATURE.) When, therefore, Scarpa supposed, that in England the practice with the circular ligature in the treatment of aneurism is materially the same now as heretofore, and that secondary hemorrhage is as frequent, he did not avail himself of all the information on the subject which he might have acquired from Mr. Wishart, the able translator of his writings on aneurism, or from an attentive perusal of Mr. Hodgson's valuable treatise.

In an equality of circumstances, conducive to the success of the Hunterian operation, Scarpa thinks that the fact is not proved, as it is presumed to be, that the rupture of the internal and middle coats of the artery does excite the adhesive inflammation and union of the artery more effectually, than is done by the simple compression and close contact of its two opposite internal parietes in a sound and uninjured state. This remark is partly true, and partly incorrect, at the same time that it involves a question, which must be deferred till we come to the article HEMORRHAGE. The truth in the observation is, that an artery may generally be rendered impervious with tolerable certainty, by compressing its opposite parietes steadily and firmly together for a certain time, without dividing its inner coats: the inaccuracy of it depends upon the fact, that surgeons have no instrument, nor contrivance (not excepting even the ligature of four or six threads, with the interposition of the cylinder of linen spread with ointment), which can retain the opposed undivided surfaces of the inner coats of the vessels closely together in the manner commended by Scarpa, and for the due time, without the objection of denuding more of the artery than need be done in the application of a small ligature; or without the serious inconvenience and risk necessarily attending the introduction of a larger quantity of extraneous matter into the wound than is desirable, with the view of averting all chance of the ulceration of the artery reaching beyond prudent limits. And, when metallic instruments are used for the same purpose, objections not less real are incurred, as will be hereafter more particularly explained.

Scarpa considers that his mode of ligature ought to be preferred, as combining the triple advantage of preserving entire all the three coats of the artery; of exciting quickly, and in a proper degree, the adhesive inflammation in them; and of retarding, as much as possible, the ulcerative process of the arterial tube.

Partly impressed, however, with the truth of the tenets laid down by Dr. Jones (see HEMORRHAGE), Scarpa enjoins attention to the following rules:—1. *Not to insulate and detach the artery any further than is necessary for allowing a ligature to be passed around it.* 2. *Not to let the cylinder of linen exceed a line in length, or a little more above and below the breadth of the tape, which is about a line for the large arteries of the extremities.* 3. *That the ligature be not too tight.* 4. *And that it be never applied immediately below the origin of a large lateral branch.* (See Scarpa, *On Aneurism*, p. 44, ed. 2.)

Some further consideration of Scarpa's mode of applying the ligature will be introduced in the article HEMORRHAGE; and I now proceed to notice his sentiments concerning the advantage which may be derived from removing the ligature

in cases of aneurism, as soon as the tube of the vessel has been obliterated by the adhesive inflammation. From the facts recorded by Scarpa, it is inferred, that, with the kind of ligature and the cylinder of linen used in his practice, the closure of the artery by the adhesive inflammation and the two internal coagula are sufficiently far advanced *on the third or fourth day after the operation*, to resist the impulse of the blood; and hence (says he) there is no rational motive for waiting beyond this time for the spontaneous separation of the ligature, or for allowing it, by its further presence, to ulcerate, and even open the artery at the principal point of adhesion. He then comments on the advantages to the wound, derived from the removal of all extraneous matter from it on the third or fourth day. With respect to the general opinion of such removal, however, he makes one exception, viz. the case of great and evident debility from sickly constitution, or very advanced age, as it is observed that, in such patients the reunion of a simple wound is frequently protracted to the sixth day. *In cases of this description, Scarpa recommends delaying the removal of the ligature to the completion of the fifth, or sixth day*, but under the express condition, that the ligature has been applied with the interposition of a cylinder of linen; as it is proved that a common circular ligature causes ulceration of the artery before the third day, and it is not till the sixth day that the external coat of the vessel begins to ulcerate, when the other modification of the ligature is adopted. (P. 50.)

Scarpa supports the preceding advice by four cases, in which his kind of ligature was applied, and withdrawn at the end of the third, or fourth day, and the arterial tube obliterated. However, I do not think that, in England, these cases, when minutely and attentively considered, will be regarded as inducements to persevere in the use of temporary ligatures. In every instance the wound is described as suppurating, and sometimes *plentifully*. In one, the foot mortified, and amputation became necessary. In another, the very day after the disturbance of removing the ligature, the thigh was attacked with erysipelas, and, on the eighth day the wound is represented as being *foul*, and the erysipelas not yet cured. It is but fair to add, that M. Roux seems to have operated on Scarpa's plan, with results much more encouraging; for he is stated to have taken up the principal arteries of the neck and limbs in this way nearly fifty times, and lost but five or six of the patients from hemorrhage or sphacelus. (See *Lisfranc, De l'Oblitération des Artères*, p. 71.)

Independently of the uncertainty of the period, when the arterial tube is closed by the adhesive inflammation in various patients, it appears to me that the disturbance of the vessel and wound, by the steps necessary for the loosening and removal of the ligature, will ever form an insuperable objection to the practice. Scarpa appears to have some apprehension of this kind himself; for he remarks: "In the act of removing the ligature, there can be no doubt it is of great consequence that the artery be not rudely handled, or stretched. And, indeed, if, on untying the running knot, the subjacent knot could be with the same facility untied, we could not wish for a better mode of performing this part of the operation. But, the knot, although a simple one, is not so readily un-

tied as the running knot, on account of the moisture with which the threads forming the ligature are soaked, or because the ligature has been previously waxed." (P. 64, ed. 2.) In fact, his apprehensions then lead him to suggest the scheme of placing, previously to making the knot, a thread longitudinally, on each side of the cylinder; and, at the time of removing the ligature, the threads are to be drawn in opposite directions, in order to undo the knot, without displacing or stretching the artery. This reminds me of the ingenious contrivance of Mr. John Barker, of Ipswich, whereby the ligature, at any period judged advisable, is removed without any disturbance of the wound: it is rendered perfectly intelligible by the annexed diagram.

Instead of one small ligature, which is all that an English surgeon leaves in the wound, Scarpa recommends his ligature of four or six threads, a roll of linen, and two other threads; a quantity of extraneous substances, which cannot fail to be a source of serious irritation and mischief. I shall therefore take leave of the proposal of removing the ligature on the third or fourth day, or any other particular day, with expressing my belief, that, if there were only the following objection to the plan it would never be adopted in this country; namely, all the advocates for this practice, excepting Mr. John Barker, whose plan has considerable merit, renounce the infinite advantage of bringing the edges of the wound together directly after the operation. Had the suggestion of Dr. Jones proved invariably correct, and the ligature admitted of being withdrawn immediately after the inner coats of the vessel had been divided by it, the case would have been very different, as there would then have been no foreign body at all left in the wound; the parts might have been immediately brought together with the greatest chance of union by the first intention, and no subsequent disturbance either of the artery, or of the wound, would have been incurred. At the same time, I admit, that if the removal of the ligature at the end of a given time should ever prove the best practice, then Mr. Barker's ingenious contrivance for undoing and extracting the ligature without any irritation of the parts, or keeping the wound open for the purpose, may become a proposal of great practical importance. At present, I am decidedly of opinion, that it is best to leave the ligature till it becomes loosened, which usually happens between the tenth and twentieth days after the operation. (See *Lisfranc, De l'Oblitération des Artères*, p. 63.)

The next practice which I shall notice, is that of applying two ligatures to the artery, and cutting it through in the interspace. This suggestion may be said to be as ancient as the time of Celsus, who advised the method to be followed in the treatment of a wounded artery. (*De Medicinâ*, lib. v. c. 26, § 21.) The fact is curious, though I mention it without the least intention of detracting

from the great merits of several modern surgeons, that the Greeks were acquainted with the practice of tying the artery with two ligatures, and dividing it between them, high above the tumor, as will appear by a reference to *Ætius*. (4 *Serm. tetr.* 4, cap. x.) In the same ancient work, we are directed to open the aneurismal tumor at the bend of the elbow, and when the blood has been evacuated, to tie the artery twice, and divide it.

This method of applying two ligatures to the artery, and dividing the vessel between them, a method spoken of by *Ætius*, was revived in France about eighty years ago by *Tenon*, who, as well as some later surgeons, was totally unacquainted with its antiquity. (See *Pelletan, Clinique Chir.* t. 1, p. 192.) At one time it had also modern advocates in *Abernethy* and *Maunoir*, each of whom supposed the plan an invention of his own. (See *Surgical and Physiol. Essays*, part iii. 8vo. Lond. 1797; and *Mémoires Physiologiques et Pratiques sur l'Aneurisme, &c.* 8vo. Genève, 1802.) Some of its advocates suspected that too rapid an ulceration of the artery and secondary hemorrhage, arose from the traction exercised in opposite directions by the upper and lower portion of the vessel; and they conceived that each end of the divided artery formed a circular prominence beyond the ligature, calculated to hinder it from slipping. Hence, according to their view, the less frequency of secondary hemorrhage after amputations, than after operations for aneurism.

When an artery is laid bare, and detached from its natural connections, and the middle of such detached portion tied with a single ligature, as was *John Hunter's* practice, *Abernethy* conceived that the vessel, so circumstanced, would necessarily inflame, and be likely to ulcerate. The occurrence of bleeding from this cause at first led to a practice, which this gentleman justly censures, viz. applying a second ligature above the first, and leaving it loose, but ready to be tightened in case of hemorrhage. As the second ligature, however, must keep a certain portion of the artery separated from the surrounding parts, and must, as an extraneous substance, irritate the inflamed vessel, it must make its ulceration still more apt to follow. The great object, therefore, which *Abernethy* insisted upon, was that of applying the ligature close to that part of the artery which lies amongst its natural connections: a just principle, the truth and utility of which still remain incontrovertible, though there may be a better way of accomplishing what *Abernethy* intended, than the measures which he was led to recommend.

The peculiarity in *Abernethy's* first operation consisted in applying two ligatures round the artery, close to where it was surrounded with its natural connections. For this purpose he passed two ligatures of middling size beneath the femoral artery; and having drawn one upwards, the other downwards, as far as the vessel was detached, both the ligatures were firmly tied. The event of this case was successful. An uneasy sensation of tightness, however, extending from the wound down to the knee, and continuing for many days after the operation, made *Abernethy* determine, in any future case, to divide the artery between the two ligatures, so as to leave it quite lax.

Abernethy next relates the particulars of a popliteal aneurism, for which *Sir Charles Blicke* operated and divided the artery between the ligatures.

The man did not experience the above kind of uneasiness; and no hemorrhage ensued when the ligatures came away, although there was reason to think that the whole arterial system had a tendency to aneurism, as there was also another tumor of this kind in the opposite thigh.

The reasoning which induced *Abernethy* to revive this ancient practice was ingenious; for, when the artery was tied with two ligatures, and divided, in the foregoing manner, it was argued that it would be quite lax, possess its natural attachments, and be as nearly as possible in the same circumstances as a tied artery upon the face of a stump. Strictly speaking, however, as *Mr. Hodgson* first pointed out, an artery tied in two places, and divided in the interspace, cannot be regarded as placed exactly in the same condition as an artery tied in amputation. In the latter case the retraction of the vessel corresponds with that of the surrounding parts, which are divided at the same instant, and therefore its relative connections stand as before the operation. But, in the operation for aneurism, the retraction of the artery takes place without being attended with a corresponding retraction of its connections. How far the retraction of the artery is beneficial, or injurious, is by no means evident; and the advantages arising from it, may, in most situations, be obtained without dividing the vessel, by placing the limb in a bent position. One important object, however, is gained by the division of the artery; namely, that it is generally in that case tied close to its connections, and it is very evident how liable the application of the ligature in the middle of a denuded extensive portion of the vessel must be to produce ulceration or sloughing of its coats. The same object, however, will be gained by tying the undivided artery close to its connections at the end nearest to the heart; and the existence of a single ligature at the bottom of the wound will be less liable to give rise to suppuration and the formation of sinuses, than the employment of two. When an artery is divided, the portions situated beyond the ligatures must slough, and prove an additional cause of suppuration in the wound. Experience has amply proved the safety of employing a single ligature, and it is at present used by many of the most experienced operators in this country. (See *Hodgson, On the Diseases of Arteries, &c.* p. 221, &c.)

According to *Scarpa*, numerous examples of the failure of the plan of applying two ligatures, and cutting through the artery in the interspace, are already generally known. He speaks of one failure which occurred to *Abernethy* himself. But I entertain doubts how far any inference against the method can be drawn from *Monteggia's* instance, in which a ligature of reserve was used. Nor can I understand how a circumstance, which *Scarpa* strongly insists upon, can be well founded; I mean, the danger of the ligature being forced off the mouth of the artery by the impulse of the blood. Any risk of this kind cannot exist if the ligature be duly applied, as *Dr. Jones* has particularly explained; and, at all events, how can it be greater here than after amputation, where it is not usually made a subject of complaint? Indeed, the several examples of secondary hemorrhage, after this method, quoted by *Scarpa* from the practice of *Monteggia*, *Morigi*, and *Assalini*, may be more rationally imputed either to reserve-

ligatures having been also used, or the common fear in Italy of applying the ligatures tightly ; in which event one can readily suppose that the ligature might really slip, or, by remaining a long time on the vessel, give rise to dangerous ulceration. Thus, Morigi speaks of one case, in which the bleeding occurred on the *nineteenth day*. (*Scarpa, On Aneurism*, p. 14, ed. 2.) On the whole I am disposed to believe that when this method has been executed precisely according to Abernethy's directions, it has not often failed ; and I am acquainted with only one case in London, in which it was followed by secondary hemorrhage. However, in the year 1807, Mr. Norman, of Bath, tied the femoral artery with two ligatures, and divided the vessel between them ; the upper ligature came away on the sixteenth day after the operation ; the lower one on the fifteenth ; and the following day a profuse hemorrhage came on, the patient losing a pound of blood. Pressure with a compress and wet bandage was continued for some time, and the wound healed. (See *Med. Chir. Trans.* vol. x. p. 123.) This is the only case of secondary hemorrhage, which Mr. Norman has met with after operating for aneurisms.

Scarpa very properly remarks, that the application of two ligatures, and dividing the artery in the interspace, can never be an eligible mode, where the smallness of the space, the depth of the artery, and the importance of the surrounding parts do not permit the vessel to be separated and insulated to such an extent as is required for dividing it, with a probability of the division of it being sufficiently distant from the two ligatures. Such, for example, are the cases of ligature of the carotid in the vicinity of the sternum ; of the iliac above Poupart's ligament ; of the internal iliac, a little below its origin from the common iliac ; of the axillary artery between the point of the coracoid process and the acromial portion of the clavicle ; or of the subclavian in its passage between the scaleni muscles. Scarpa then comments on the difficulty, and even impossibility, of taking up the end of the truncated artery again in many situations, were hemorrhage to ensue ; and he joins Mr. Hodgson in thinking the advantages of the method, even where it is practicable, by no means demonstrated. Nay, he goes further ; for he agrees with Heister, Callisen, and Richter in setting it down as worse than useless, on account of the portion of the artery between the ligatures being converted into a dead and putrid substance, which rests upon the bottom of the wound, from which it cannot be removed until the two ligatures are separated. Here, deeply impressed with the truth of principles, which, perhaps he has rather lost sight of in speaking of his own particular method, he comments on the little probability of the wound uniting, under the disadvantage of two ligatures hanging out of it, and of sloughs at its bottom. He argues correctly, that the laying bare, and insulating a large portion of artery, would often be objectionable on the ground that it could not be done without the surgeon being obliged to apply the principal ligature too near the origin of a large lateral branch ; as would happen in a case of femoral aneurism, situated *an inch and a quarter* below the origin of the profunda. Thus, a coagulum could not be formed, and the artery would be in danger of not being closed. On the contrary, by employing only a single ligature, at *an inch and a quarter*

below the origin of the profunda, the operation would be simple and successful. (*Scarpa, On Aneurism*, p. 19—21, ed. 2.)

The above considerations would certainly lead me to avoid the practice of detaching an artery from its surrounding connections any more than is absolutely necessary for the conveyance of a single ligature under it ; but I fully concur with Sir Astley Cooper in the prudence of using two ligatures, and applying them in the way recommended by Mr. Abernethy, whenever the artery has been extensively separated from its sheath in the operation.

The frequent occurrence of accidents after the introduction of Mr. Hunter's operation might have been ascribed to more probable causes than the condition of an undivided artery, upon which the ligature was applied. The employment of numerous ligatures gradually tightened, or the introduction of extraneous bodies into the wound, were alone sufficient to produce ulceration of the artery : and such practices were adopted in most of the cases in which secondary hemorrhage took place.

After the reasons which have been specified against the plan of tying the artery with two ligatures, and dividing it in the interspace, it may appear superfluous to notice a modification of this practice, intended as a security against the slipping of the ligature. But, as the proposal has had the approbation of some men of eminence, the subject may still be worthy of notice.

Sir Astley Cooper published a case of popliteal aneurism, in which the femoral artery had been tied with two ligatures, as firmly as could be done without risk of cutting it through. "But (says he) as I was proceeding to dress the wound, I saw a stream of blood issuing from the artery, and when the blood was sponged away, one of the ligatures was found detached from the vessel. Soon after, the other was also forced off ; and thus the divided femoral artery was left without a ligature, and unless immediate assistance had been offered him, the patient must have perished from hemorrhage." The same kind of accident occurred in Mr. Cline's practice. For the prevention of it, Sir Astley at first tried the method of conveying the ligatures, by means of two blunt needles, under the artery, an inch asunder, and close to the coats of the vessel, excluding the vein and nerve, but passing the threads through the cellular membrane surrounding the artery. When these were tied, and the artery had been divided between them, the ligatures were prevented from slipping by the cellular membrane through which they passed. Afterwards, however, he tried a different mode of securing the ligature, suggested to him by Mr. H. Cline. "An incision being made on the middle of the inner part of the thigh, and the femoral artery exposed, the artery was separated from the vein and nerve, and all the surrounding parts, to the extent of an inch ; an eye-probe, armed with a double ligature, having a curved needle at each end, was conveyed under the artery, and the probe cut away. The ligature nearest the groin was first tied ; the other was separated an inch from the first, and also tied. Then the needles were passed through the coats of the artery, close to the ligatures between them, and the ends of each thread were again tied over the knots made in fastening the first circular ap-

plication of the ligatures. Thus, a barrier was formed, beyond which the ligature could not pass." This operation was successful. (*Med. and Phys. Journ.* vol. viii.) A similar proposal appears to have been mentioned by Dionis, and some subsequent writers, especially by Richter, in the 13th chapter of his *Anfangsgründe der Wundarzneykunst*, b. i. ed. 3, 1799.

The preceding method is so contrary to the grand principle of always avoiding the detachment of the artery from its surrounding connections, and is so inconsistent with the wise maxim of completing the operation with as little disturbance of the vessel as possible, that it is not surprising that it should have met with only a small number of followers. In fact, it is not only liable to every objection which can be urged against the double ligature and division of the artery, as formerly proposed by Celsus, and a few of the moderns, but on account of its greater tediousness, more extensive separation and destruction of the vessel, and other reasons, is still less worthy of imitation.

Where ligatures slip off directly after their application, I conclude that the arteries either cannot have been tied with sufficient tightness, or else that the noose becomes slack, from causes which will be understood by considering what is said on this matter in the article HEMORRHAGE. The inner coats of the artery, we know from the experiments of Dr. Jones, ought to be cut through when the artery is properly tied, because the circumstance is always useful in promoting the effusion of lymph within the vessel, and the process of obliteration by the adhesive inflammation: it may also be advantageous in keeping the ligature from slipping.

With respect to ligatures of reserve, the interposition of agaric, cork, and other hard substances between the knot and the artery, these contrivances are now so fully rejected by all good surgeons, for reasons which will be quite intelligible after the perusal of another part of this work (see HEMORRHAGE), that I shall not at present detain the reader with animadversions on their danger. As for several kinds of metallic compressors intended to be applied to the exposed artery, for the purpose of rendering it impervious, they are inventions which have been made and extolled by some surgeons of high repute, whose names would give importance even to a less meritorious proposition.

Dubois conceived that hemorrhage might sometimes proceed from the circumstance of a ligature making its way too fast through the artery. He thought also that the sudden stoppage of the current of blood by a tight ligature might bring on gangrene of the limb, particularly when the aneurism was not of long standing, so that the collateral branches had not had time to enlarge. Dubois, therefore, proposed a method of *gradually* stopping the flow of blood through the artery; and by this ingenious imitation of the process of nature, to promote the gradual dilatation of the collateral arteries, and obviate all risk of gangrene in the lower part of the limb. This gentleman put his plan in execution, and two instances of success are recorded. The cases were popliteal aneurisms. A ligature was passed under the artery in the manner of Hunter; its two ends were then put through an instrument called a

serre-nœud, with which the compression was gradually increased. It is stated that, in one of these cases, the plan made the artery inflame and become impervious, in the course of the first night, so that on the following day the throbbing of the tumor had ceased. (*Richerand, Nosogr. Chir.* t. iv. p. 109, edit. 4.) Here, however, it is to be suspected that the pressure of the apparatus was greater than was calculated: and that the stoppage of the pulsation was more owing either to this cause, or to the coagulation of the blood, in the sac and adjoining portion of the artery, than to the process of obliteration, which could hardly have been so rapidly accomplished.

Assalini's compressor is an instrument, calculated, as its inventor states, to produce an obliteration of the trunks of arteries, without dividing or injuring their coats. It is nothing more than a small pair of silver forceps, the blades of which are broad and flat at their extremities, between which the artery is compressed. A spring, composed of a piece of elastic steel, is attached to the inside of one of the handles, and, by pressing against the opposite handle, retains the flat ends of the blades in contact. This spring is intended to be very weak in its operation; but, by means of a screw which passes through the handles, the pressure admits of being regulated and increased at the option of the surgeon.

A representation of Assalini's compressor may be seen in his *Manuale di Chirurgia, parte primâ*, p. 113. In the same book, or in my friend Mr. Hodgson's valuable *Treatise on the Diseases of Arteries and Veins*, which every practical surgeon ought to possess, a case may be perused, in which this instrument was successfully employed by Professor Monteggia, and withdrawn entirely, as early as sixty hours after its application. This last distinguished surgeon also used the compressor in an example, in which the femoral artery was wounded, and bled in an alarming degree. After forty hours, the pressure was lessened; and, in four hours more, as not a drop of blood issued from the vessel, and there seemed to be no good in leaving an extraneous body in the wound any longer, the instrument was taken out altogether. (See *Assalini's Manuale di Chirurgia*, p. 110.)

When Assalini was in England, he acquainted Mr. Hodgson, that in two cases of popliteal aneurism, in which he had himself employed this means of obliterating the femoral artery, the instrument was removed at the expiration of twenty-four hours; no pulsation returned in the tumors; and the patients were speedily cured.

With respect to the particular merit of this invention, it certainly possesses the recommendation of ingenuity: but it operates much in the same manner as several other mechanical contrivances of the *serre-nœud* of Dessault, the *presse-artère* of Deschamps, that of Mr. Crampton (see *Med. Chir. Trans.* vol. vii.), the pincers of Baron Percy, &c. If there be a real advantage in the division of the internal coats of an artery by the ligature, as the experiments of Jones seem to prove, and as many of the best surgeons in this country inculcate (see HEMORRHAGE and LIGATURE), then the compressor cannot be an eligible means of obliterating an artery. It may be said, however, that experience has proved its efficacy; but, let it be recollected that almost every method of operating upon aneurisms has sometimes

answered. Further experience is requisite to determine whether Assalini's compressor would succeed as often as, or more frequently than, the scientific application of the right kind of ligatures (see *LIGATURE*), which may perhaps seem slower in their effect, only because they are not in general removed as early as Assalini's instrument. In fact, the experiments of Mr. Travers have now proved that the ligature is the quickest in its operation. (See *Med. Chir. Trans.* vol. vi. p. 643, &c.)

In 1816, some ingenious observations were published by Mr. Crampton, on the effects of the ligature and of compression in obliterating arteries. The purport of his remarks is to prove, like the later observations of Scarpa: 1st, That the obliteration of an artery can *very certainly* be effected, independently of the rupture or division of any of its coats; 2ndly, That this operation of the ligature, so far from being essential to the process, not unfrequently defeats it. (See *Med. Chir. Trans.* vol. vii. p. 344, 345.)

With respect to the first of these assertions, I presume, that all practical surgeons have known and admitted it, especially if the words *very certainly* be left out. Every system of surgery, for half a century past, has recorded the occasional cure of aneurism by different modes of compression by which the adhesive inflammation is excited in the artery, or the coagulation of the blood in the aneurismal sac brought about. As, however, the most experienced surgeons have found the method less certain than the use of the ligature, it is not represented, by any modern writers, as deserving equal confidence; though there are circumstances in which simple pressure may be sometimes tried, with the hope of doing away all occasion for an operation. The cases, however, in which compression is applied directly to the artery itself by means of ligatures, with the intervention of other substances, as advised by Scarpa, &c., or by various contrivances, like those of the *serre-nœud*, the *presse-artère*, and Assalini's forceps, all require the exposure of the artery; and if commendable, therefore, cannot be so on the principle of saving the patient the pain of an operation, but because they are more effectual than the employment of the ligature. This last point remains to be proved. From the comparatively small number of instances, in which the preceding modes of compression have been practised, several examples of failure might be quoted.

With regard to Mr. Crampton's second assertion, that the division of the inner coats of the vessel, so far from being essential to the process of obliteration, not unfrequently defeats it, I think the last part of the observation is altogether unproved. We must admit, that the division of the inner coats is not essential, because arteries sometimes become obliterated under a variety of circumstances in which such division is not made; but still, the great question remains, whether it renders the process more certain. Mr. Crampton founds his conclusions, that it not unfrequently prevents the obliteration, and gives rise to secondary hemorrhage, upon a very few uncommon cases in which aneurismal swellings have taken place above the ligature. (See *Warner's Case*, p. 156, of this Dictionary.) Here Mr. Crampton presumes that the occurrence happened from the division of the inner coats of the artery,

though Warner himself suspected, with more probability, that it proceeded from a diseased state of the vessel. Besides, this event, be it produced in whatever manner it may, is so rare, that I only know of three examples of it on record, and have never known it occur during the many years that I have been in the constant habit of seeing numerous operations performed. In Warner's time, also, the ligatures used were so thick, that they must have been more likely just to press the sides of the artery together, like Mr. Crampton's *presse-artère*, than effect a complete division of the inner coats of the vessel, as is accomplished by the small ligatures in modern use.

Those metallic instruments, intended to be applied directly to an exposed artery, for the purpose of obliterating it by compression, are liable, as Scarpa remarks, to all the inconveniences which are inseparable from the presence of hard bodies, introduced and kept for several days in the bottom of a wound; especially when this is recent, in which case they cannot be retained in a proper direction without difficulty, or exactly at such a depth as will not be attended with hurtful pressure upon the wound itself, and important parts in its vicinity. And, with regard to the forceps of Assalini, Monteggia has observed, "*If the obliteration of the artery is retarded, the forceps equally divides the artery by causing the death of the included portion. I also saw, in one case, the extremity of the instrument resting at the bottom of the wound on the subjacent femoral vein, rupture its anterior half also, although we were sure it had not been included by it.*" (*Instituz. di Chir.* ed. 2, t. ii.) And although Cumano, in a case of popliteal aneurism, obtained, on the fourth day, the closure of the femoral artery, by means of Assalini's forceps, he does not conceal that the cure of the wound was rather difficult; and, in comparing the ligature with the forceps, he adds his belief, that if an equal result is derived from both, the preference will be given to the ligature, unless the other instrument be brought to such perfection that the inconveniences will be removed from which he found it not exempt, though the operation succeeded. (*Annali di Med. del Dottore Omodei*, Settembre, 1807, p. 309; and *Scarpa, On Aneurism*, p. 45, ed. 2.) Some experiments were a few years ago instituted by Mr. Travers, in order to determine the merit of Assalini's forceps, compared with the ligature; and his conclusions from the facts elucidated in the investigation is, that the ligature is a more powerful means of effecting the obliteration of the tube of an artery. (See *Med. Chir. Trans.* vol. vi. p. 643, &c.)

The substance called silkworm gut, used by anglers, was proposed to the profession for securing arteries, in the year 1818. (See *Experiments in favour of a new substance for tying Arteries, and for Suture*, by Joseph M'Sweeny, M.D. in the *Edinburgh Medical and Surgical Journal*, vol. xiv. p. 597.) It is described as round, smooth, amazingly strong, only as thick as horse-hair, thus adapted for cutting the internal coat of an artery; and it admits of being firmly knotted when moistened. In all the experiments where it was used, the wound healed kindly over it, and on killing the animal it was found unchanged. In the year 1826, Mr. Fielding drew the attention of surgeons to the subject of silkworm gut, not aware of Dr. M'Sweeny's experiments. This substance was employed for

securing arteries, in various operations, with complete success ; the wounds healed quickly over it, Mr. Fielding has the merit of having first used it successfully in operations on the *human body*. (See *Trans. of the Medico-Chirurgical Society of Edinburgh*, vol. ii. p. 340.)

A few years ago, Mr. Lawrence extended to operations for aneurism the method of tying the artery with a small firm silk ligature, the whole of which is immediately afterwards cut off, with the exception of the noose and knot, and an endeavour then made to heal the wound by the first intention. In a case of popliteal aneurism, Mr. Carwardine, late of Thaxted, tied the femoral artery in this manner, and the wound united entirely by the first intention, not a particle of pus having been formed at any time ; and the part continued perfectly sound at the distance of some months from the operation. On the 29th of March, 1817, I saw Mr. Lawrence try the practice in a similar case : with the exception of the integuments, the wound united by adhesion. However, it continued to discharge a small quantity of matter till the end of May, when the ligature came away, and it healed firmly. In an aneurism of the brachial artery, Mr. R. Watson, of Stourport, Worcestershire, tied that vessel and cut off the ends of the ligature, as proposed by Mr. Lawrence. The operation was done on the 2nd of March, and the wound was quite healed by the 10th of April. On the 3rd of May, a small tubercle which had been felt under the skin in the centre of the cicatrix, appeared above the skin, and proved to be the knot of the ligature. There was no inflammation, nor discharge ; but the ring of the ligature was firmly impacted in the centre of the cicatrix. In about a week from this time, the whole of it was expelled. In another case, where Mr. Hodgson tied the ulnar artery, and cut off the ends of the small ligature, the skin healed over the vessel, but a firm almost cartilaginous knot gradually formed, from the centre of which the bit of ligature was extracted five or six months afterwards by a small puncture. (For additional observations, see *Med. Chir. Trans.* vol. viii. p. 490, &c.)

Although Mr. Carwardine's case is a strong one in favour of this method, I apprehend that, on the whole, the cures on record thus effected cannot be said to have been completed sooner than others generally have been, in which one end of the small circular ligature was left for the removal of the noose. Thus, in two cases, where the practice was tried by Mr. Norman, of Bath, the results were by no means encouraging. In one of these instances, a part of the wound appeared to have united by the first intention, but *matter afterwards formed, and it was a considerable time before the ulcer healed*. The ligature was never seen to come away ; but from the circumstance of the suppuration, Mr. Norman apprehends that it must have been voided. In a second example, the attempt to procure a permanent adhesion of the parts over the ligature did not succeed ; a *long and troublesome suppuration ensued*, and the wound was not healed till the latter end of April, though the operation was done on the 7th of March. (Norman, in *Med. Chir. Trans.* vol. x. p. 120, 121.) As catgut, however, was employed for the ligatures in these two operations, I do not know that it is fair to consider the method exactly

like that recommended by Mr. Lawrence, who particularly directs very small ligatures of dentist's silk to be used. But, besides the different material employed, we are left uninformed of the thickness of the catgut ; and, in this respect, also, there would probably be no greater similarity between the ligatures of these gentlemen than there was in regard to the substances of which such ligatures were made. In favour of catgut as a ligature, when the ends of it are to be cut off, a case published by Sir Astley Cooper deserves particular notice. The wound was found completely united on the fourth day after the operation, notwithstanding the patient was eighty years of age. The catgut, previously to its application was softened in warm water. The recovery was complete ; a fact, strongly proving the propriety of not rejecting an operation on account of age, if no other objection exists. (See *Surgical Essays*, part i. p. 126.) Sir Astley afterwards renounced both the use of catgut ligatures, and the plan of cutting off both ends of each ligature. With respect also to silk ligatures, it seems that little abscesses and hard knots occur even after their use in this manner, and these inconveniences have deterred surgeons generally from adopting the innovation. M. Manec tried the plan with ligatures composed of various animal substances, silk, catgut, filaments of nerves, tendons, &c. ; and the result was, that the wound was never healed by adhesion over the extraneous substance, without abscesses afterwards forming for its discharge. Dupuytren observed the same thing. Lisfranc was a witness of two cases, in which the ligature was not absorbed, and severe consequences ensued. (*De l'Oblitération des Artères*, p. 55.) Some American surgeons, and especially Drs. Physic and Levert, tied the artery with lead, gold, silver, or platina wire, and then cut off the ends of such ligature. They were led to adopt this plan by the consideration of the little irritation sometimes resulting from the presence of a metallic substance in the textures of the body, as illustrated in gunshot wounds. In experiments on animals, the artery was obliterated by the metallic wire, the part of which, left in the wound, became included in a kind of little cyst, where it remained without inconvenience. It does not appear that the practice was ever tried on the human subject. However, I join Lisfranc in the belief, that if it were tried, it would be found liable to the objections urged against silk and catgut ligatures used in this way. (*De l'Oblitération des Artères*, p. 57.) Be it recollected, also, that a bullet, or other metallic body, only occasionally lies in parts without causing inconvenience : much more frequently it tends to make its way outward, and bring on suppuration and ulceration. I coincide, then, with M. Lisfranc, and the great body of English and French surgeons, that, as the plan of removing both ends of the ligature brings no advantage to counterbalance its inconveniences, it should be relinquished, and the preference given to the method of cutting off only one end, and leaving the other hanging out of the wound. (Op. cit. p. 58.)

In cases of aneurism, a single small ligature, composed of dentist's silk, common silk, thread, inkle or twine, is now usually preferred by the majority of surgeons in England ; but, as the right qualities of ligatures are elsewhere considered (see HEMORRHAGE and LIGATURE), I need not here dwell upon

the subject. It is not meant to assert, that the use of a single ligature is never followed by secondary hemorrhage; for this would be untrue. The accident, I believe, will sometimes happen after this or any other mode, under certain circumstances, and in unfavourable subjects. A fact of this kind we find recorded, which happened in the practice of a truly eminent and experienced surgeon (see *A. Burns, On Diseases of the Heart*, p. 230); but, it appears to me, that, *cæteris paribus*, a single small ligature, applied with as little disturbance and detachment of the artery as possible, will be more rarely followed by secondary hemorrhage, abscesses, sinuses, &c., than any other known method. Thus, in the several cases reported by Mr. Norman, the single ligature was never followed by any of those inconveniences which, he justly thinks, will be rarer after this practice than any other, "if the artery be not removed from its situation, or more detached, than the ligature separates it." (See *Med. Chir. Trans.* vol. x. p. 123.)

I have already insisted on the importance of tying a sound portion of the artery. Even a dilatation of it, unattended with calcareous or atheromatous depositions, is unfavourable to the success of the ligature. M. Lisfranc, in one instance of carotid aneurism, had only room for a ligature on a dilated portion of the common carotid, between the aneurism and the sternum: in a few days the artery gave way below the ligature, which had not quitted its place. (See *Lisfranc, De l'Oblitération des Artères*, p. 65.)

Before entering into the consideration of particular aneurisms, I wish to mention a few other circumstances, worthy the attention of every practical surgeon. The first is, the partial entrance of blood into the aneurismal sac, after the artery has been tied at some distance from the tumor. This fact was first particularly pointed out, and its reasons explained, by Sir E. Home, who published three examples of its occurrence. (See *Trans. for the Improvement of Med. and Chir. Knowledge*, vol. i. p. 173, and vol. ii. p. 239.) But I believe that it had never been considered with due attention, until Mr. Hodgson made it one of the subjects of his reflections in his valuable treatise.

"When an artery is tied close to an aneurismal sac, the ingress of blood into the latter is in most instances prevented; the coagulum which it contains is absorbed, and the membranes of which the sac is composed gradually contract, until its cavity is permanently obliterated. But when the artery is tied at a distance from the disease, the ingress of blood into the latter is not altogether prevented; for, the anastomosing branches, which open into the trunk below the seat of the ligature, convey a stream, which passes through the aneurism. The impulse of this current, however, is so trifling, that the enlargement of the sac not only ceases, but the deposition of coagulum in it increases, in consequence of the languid state of the circulation. The coagulum accumulates, until the cavity of the sac, and the mouth of the artery leading into it, are obliterated," &c. (See *Hodgson, On the Diseases of Arteries*, p. 266.)

This fact, which is of great importance, both in a practical and pathological point of view, is proved (says this gentleman), 1st, by the occasional recurrence of pulsation in the tumor after the operation; 2ndly, by cases in which the cavity

of the sac has been exposed, and hemorrhage has been the consequence; and, 3rdly, by dissection, in which it has been found, that the cavity of the aneurism, as well as that of the artery from which it originated, was pervious, from the part which was obliterated by the direct operation of the ligature. For a detail of the facts relative to this interesting point, the reader is referred to Hodgson's valuable publication (p. 267, *et seq.*)

Some very uncommon instances are recorded, in which the return or continuance of pulsation in the tumor is said to have prevented the cure; the aneurismal sac having begun to enlarge again. The two cases of this kind, however, which happened in the practice of Pott and Guerin (*Trans. of a Soc. for the Impr. of Med. and Chir. Know.* vol. i. p. 172; and *Journ. de la Soc. de Santé* No. 3. p. 197), cannot be well depended upon, as it may be doubted whether the artery was really tied. Some better established facts, relating to this part of the subject, have been very recently published. One is a case by Dr. Monteath, jun., of Glasgow, which is very remarkable, as the disease, viz. a popliteal aneurism, occurred nine months after the femoral artery had been unequivocally tied in the upper third of the thigh. On the 27th of February, 1819, this gentleman performed the operation, using a single ligature; the pulsation of the tumor in the ham instantly ceased; and the wound healed by the first intention, except where the ligature was situated, which came away on the thirtieth day. By this time the tumor was diminished to one half of its original size, and, in two months more, only a hard knot was perceptible, in which no pulsation whatever could be felt. After the considerable lapse of time above specified, the patient informed Dr. Monteath, that the tumor had reappeared, being rather larger than a plum. The pulsation in it was distinct, though not so strong as in ordinary aneurism. As the size of the swelling, and strength of the pulsation, increased gradually, a compress and bandage were applied, without confinement; but, as this treatment was ineffectual, the patient was afterwards kept in bed, bled, and put on a spare diet. A thick compress was placed over the tumor, and the limb was firmly bandaged from the toes to the groin. A trial of this plan for three days not having produced any benefit, a tight tourniquet was applied over the tumor; but the pain was such in half an hour, that the instrument was taken off, from which moment no pulsation was felt. Next day the tumor not only did not throb, but had a firm feel; and, the bandage being continued, the cure was gradually completed. Had the disease not yielded to these means, Dr. Monteath meant to have tied the inguinal or external iliac artery, with the view of cutting off the supply of blood to the sac, through the anastomosing branches. (*Scarpa, On Aneurism, by Wishart*, p. 510—512, ed. 2.)

The following cases were mentioned by Sir Astley Cooper:—A man underwent the operation for aneurism; the femoral artery was tied; the pulsation ceased; and the patient in a little while was supposed to be cured of the aneurism, and discharged. Upon his return to labour, however, a swelling arose in the ham, without pulsation. The swelling subsided in consequence of rest; but afterwards, while the man was at work, the swell-

ing returned with great pain. At length, as Sir Astley conceived that there was no prospect of the limb becoming useful again, it was amputated. Upon an examination of the parts, he found that the femoral artery, below the place of the ligature, had been conveying blood. It does now and then happen (says he), that a blood-vessel will arise from the artery close above the ligature, and pass into the artery immediately below it, by which means the circulation is produced. Sir Astley then referred to a specimen in the hospital museum, where this fact is illustrated in the brachial artery. (See *Lancet*, vol. i. p. 298.) Mr. Jeffreys had a gardener under his care in St. George's Hospital, who had been operated upon by Mr. Gunning for a popliteal aneurism four years previously, and which appeared to have been cured; but the tumor returned a few weeks before the patient's re-admission. The limb was amputated, but the result was fatal. In the *post mortem* examination, the femoral artery was found obliterated for the space of half an inch, at the part where the ligature had been applied four years previously; and immediately below the impervious part, two branches, equal to half the diameter of the femoral artery, were observed to enter the continuation of that trunk. It was inferred, that the circulation through the aneurism had never been wholly suspended, and that the disease was a reproduction of the original tumor. (See *Guthrie, On Dis. of the Arteries*, p. 157.)

The external iliac artery was taken up by Mr. Norman of Bath, for the cure of an inguinal aneurism; and when the collateral circulation was fully established a few days after the operation, the tumor was again supplied with blood in sufficient quantity to produce a distinct pulsation; "a fact (says Mr. Norman) of practical importance, as it shows, that though the ligature on the iliac artery stops the direct influx of blood into the tumor, and is the means by which the disease is cured, yet that there exists a necessity for employing strict rest, the antiphlogistic regimen, and, in some cases, the abstraction of blood, to assist nature in her operation of obliterating the aneurism." And, in another instance, after the same gentleman had tied the femoral artery for the cure of popliteal aneurism, the pulsation, though stopped for a time in the tumor, afterwards recurred in such a degree, that much doubt was entertained whether the disease would have been cured by the ligature on the femoral artery, had not continued and rather powerful pressure been adopted. (*Med. Chir. Trans.* vol. x. p. 99, 118, &c.) Mr. Briggs also had a case exemplifying the recurrence of a popliteal aneurism some time after an apparent cure by the operation, and the successful employment of pressure on the artery in bringing about a permanent stoppage of the renewed pulsation, and the removal of the tumor. (See *Guthrie, On Dis. of the Arteries*, p. 157.) Another instance of the good effect of this practice, I shall presently notice: it was in a case under Mr. Liston.

[The continuance or return of pulsation in the sac after the ligature of an artery, is an interesting phenomenon. In most of the cases in which it has occurred, a thrill or pulsation has been felt in the artery within twenty-four hours after the application of the ligature. In other instances it has not occurred until a month or six weeks have elapsed; and in a few examples not until after some months

have passed, when a *secondary* aneurism has formed. The aneurismal sac may slowly and gradually enlarge, without pulsation, after the application of the ligature, owing to the influx of regurgitant blood.

Recurrent pulsation usually ceases of itself. Should it not do so, the application of a compress or bandage will usually suffice to ensure the consolidation of the aneurism. If it recur at a late period, constituting a secondary aneurism, there would probably be no resource but amputation.

Suppurative sloughing of the aneurismal sac after the application of the ligature, is chiefly apt to occur when the disease is seated in the axilla, groin, or neck. It may prove fatal by the occurrence of secondary hemorrhage.

When an aneurism has suppurated or burst, the patient is in danger of dying from the immediate occurrence of hemorrhage from the sac. Should this not supervene at once, a tourniquet should be applied around the limb, and the sac being cleared of all coagula, and freely laid open, must be methodically plugged from the bottom, and a graduated compress firmly applied over it. In this way the bleeding may be checked and permanently arrested. Should it still recur, the actual cautery should be applied. The attempt to confine and to secure the bleeding vessel by a ligature has, I believe, ever been attended by successful results.

Gangrene of the limb may happen either from the large size of the aneurismal tumor compressing, and thus interfering with the circulation through the anastomosing vessels, or else by an obstruction being occasioned by the release of the venous blood in consequence of the incorporation of the contiguous vein on the wall of the sac. Sometimes it may occur from erysipelas, or from the tendons of an inflamed sac. Under such circumstances, incision of the sac, and letting out the contents, has saved the limb. But when gangrene has once fairly set in, there is no resource but amputation high up.]

With respect to the circumstance of hemorrhage being more likely to follow, when the ligature is placed close below, than at some distance from a great collateral artery, there cannot be a doubt of the fact. M. Roux, when in London, saw an occurrence of this kind himself, and has published it in his book. It was a case in which Sir Astley Cooper tied the external iliac artery; but the patient died of hemorrhage a fortnight afterwards, and, on opening the body, it was ascertained that the obturator artery, which usually arises either from the trunk of the internal iliac, or from the epigastric, proceeded from the external iliac, and arose immediately above the point to which the ligature was applied. (See *Parallèle de la Chir. Angloise avec la Chir. Française*, &c. p. 278, 279.)

From a preparation, spoken of by Mr. Travers, from others in different museums, especially in that of the University College, and from some experiments which were made, it would appear that the presence of a collateral branch hinders the formation of the internal coagulum, but will not always prevent the closure of the vessel by the adhesive inflammation. In the preparation referred to by Mr. Travers, a ligature was applied to the external iliac, between the epigastric and circumflex iliac arteries, "and having been in contact with the former at the angle which it makes at its

origin from the iliac, ulceration had taken place, and the bleeding had proved fatal. *There was no coagulum formed in the iliac trunk*, though the operation had been performed several days, the circulation through the epigastric having continued. *But the lymph-plug at the seat of the ligature on the iliac artery was complete.*" (*Med. Chir. Trans.* vol. vi. p. 656.) Indeed, it must be admitted that the fluidity of the blood does not prevent the adhesive process, a fact which, as Mr. Travers observes, is also proved by the indirect obstruction of a vessel, by means of a temporary ligature, or compressor. When, therefore, the vicinity of a large branch to the ligature is spoken of as a circumstance conducive to secondary hemorrhage, I mean that it is so, inasmuch as the internal coagulum is useful in promoting the closure of the vessel, and its formation is prevented.

It was either Brasdor or Desault, who first conceived, that, when an aneurism was so situated, that a ligature could not be applied to the artery leading to the swelling, a cure might possibly arise from tying the vessel on that side of the tumor, which was most remote from the heart. Desault conjectured that, by this means, the circulation through the sac would be stopped, the blood in it would coagulate, that the circulation would go on by the collateral arteries, and that the tumor would be finally absorbed. Deschamps tied the femoral artery below an inguinal aneurism; but the progress of the disease, instead of being checked, seemed to be accelerated by the experiment. The operator was obliged, as a last resource, to open the tumor, and try to take up the vessel. In this attempt the patient lost a large quantity of blood, and died eight hours afterwards. (See *Œuvres Chir. de Desault par Bichat*, t. ii. p. 563; and *Recueil Périodique de la Société de Médecine de Paris*, t. v. No. 17.)

The operation of tying the artery below the tumor was repeated by Sir A. Cooper, not for an aneurism of the femoral artery in the groin, but for an aneurism of the external iliac, where tying the artery above the swelling was impracticable. The femoral artery was therefore tied immediately below Poupart's ligament, between the origins of the epigastric and the profunda. The pulsations of the tumor continued; but the progress of the disease was checked. After a time, indeed, the swelling decreased, and this in so considerable a manner, that hopes began to be entertained that perhaps the external iliac artery might soon admit of being tied above the disease. The ligatures came away without any unfavourable occurrence; and when the wound was healed, the patient was sent into the country for the benefit of the change of air. Afterwards, however, the tumor gave way; an extravasation of blood took place in the cellular membrane of the pelvis, and the patient died. Sir A. Cooper had no opportunity of seeing the case; and as the body could not be opened, further particulars were not obtained.

I believe no additional trials of this practice were made in any part of the world, and that, in fact, the general feeling of the profession was decidedly against it until my friend Mr. Wardrop directed his particular attention to the subject, and both by reasoning and facts exemplified, that Brasdor's method of operating ought to be adopted in certain aneurisms, the circumstances of which forbid the application of a ligature on the cardiac side of

the tumor. The pulsation, which is sometimes felt for the first few days, at length subsides, in consequence of the circulation being stopped by the increased quantity of coagula, and the tumor begins to diminish. It is from facts of this kind that Mr. Wardrop deduces what he calls "a new principle for operating in aneurisms, so situated as hitherto to have been considered beyond the reach of art, and to which the Hunterian principle of operating is totally inapplicable." (*On Aneurism*, p. 15, 8vo. Lond. 1828.) Mr. Wardrop observes, that the changes produced by Brasdor's method, both in the artery and the sac, are precisely those which Nature employs when she cures the disease by a spontaneous process. No sooner is the ligature applied on the distal side of the aneurismal tumor, than, as after the Hunterian plan, the anastomosing vessels dilate, and perform the function of the obliterated or obstructed trunk. The cases in which the operation has been done, prove also what would not have been expected, that the tumor, directly after the application of the ligature, diminishes, instead of undergoing enlargement. "If the circulation be turned into a new channel, and if that channel completely fulfil the purpose, the sac, with its contents, as well as the portion of artery extending between the aneurism and the ligature, and also the blood contained in it, will now be in a passive state; and though the blood will continue, for a certain time, to be influenced by the impulse of the circulation, carried on in that part of the vessel which passes into the tumor, still its motion must become not only languid, but its current irregular, a state which, we know, admits of its speedy coagulation. Whenever the coagulation of the blood does take place, then the cure of the aneurism may be said to be accomplished; the sac will contract; the coagulum will be absorbed; some portions in contiguity with the sac will become organised, and consolidate; others, if the quantity be very large, will escape by a process of ulceration through the skin; and ultimately a gradual coalescence of the tumor will thus take place." (*Wardrop*, p. 20.) In the summer of 1825, this gentleman first tried Brasdor's method. The case was a carotid aneurism, in a female seventy-five years of age. The disease was so close to the clavicle, that it was quite impracticable to tie the vessel on the cardiac side of the tumor. Immediately the artery was tied, the swelling underwent a diminution. On the fourth day, it had lessened by one third. Afterwards the throbbing continued strong for a few days, at the expiration of which it became obscure, and at the same time the tumor began to diminish again. Previously to the complete cure, ulceration occurred, and several large masses of coagulated blood were discharged, along with some healthy pus. Three years after the operation, the patient continued to enjoy good health.

December 10, 1826, Mr. Wardrop attempted a similar operation for the cure of a carotid aneurism in another woman aged fifty-seven. Some reduction of the throbbing, and other relief, are stated to have ensued; but the patient died of a complication of complaints on the 23rd of the following March, 1827. "Up to the day of her death, a tumor remained in her neck, of about the bulk of an almond, which pulsated strongly, felt very thin in its coats, and its contents could be readily

squeezed out of it, but returned rapidly when the pressure was removed." (P. 33.) In the dissection it deserves notice, that *the carotid was found completely pervious, and that no cicatrix, nor other appearance, enabled Mr. Bennett to ascertain the precise point to which the ligature had been applied.* (P. 35.) These circumstances might raise a doubt about the artery having been tied at all; but, supposing the ligature to have been duly applied, they prove to my mind the failure of the operation, inasmuch as the tumor and carotid artery were probably in almost the same state as if nothing had been attempted. The blood passed freely through them, and was not compelled to circulate through new channels. Without wishing however, to enter into the question whether the artery were tied or not, I shall dismiss this example with two plain inferences: first, that, if the artery were tied, the operation failed to bring about the desired obliteration of the vessel, and coagulation of the blood in the swelling; secondly, that if it were not tied, what was done is neither favourable, nor unfavourable, to the practice of which we are now considering the merits. A third example of the operation is reported in vol. xii. of the *Lancet*. The carotid was tied above the aneurism by Mr. Lambert, March 1st, 1827, in the presence of Mr. Wardrop, Mr. B. Cooper, and Mr. Calloway. On the third day the tumor seemed much consolidated and reduced in size. On the tenth day, there was some bleeding from the wound; but it was suppressed by the application of a compress wet with cold water; and in a few days the swelling had entirely disappeared, and all that could be felt of it, on pressing the finger deeply down, was a small hard tumor, having a very faint undulatory thrill. Unfortunately, this patient, also a female, fell a victim to hemorrhage on the 1st of May, in consequence of ulceration extending from the cicatrix through the platysma myoides to the artery. Without detailing other appearances noticed in dissection, suffice it to mention, that "at the root of the right common carotid artery was a consolidated tumor, of a pyramidal shape. A probe could not be passed upwards from the arteria innominata, and water forcibly injected at this part would not pass, so completely and effectually closed was the lower part of the carotid artery. On making a longitudinal section of the tumor, we observed at its lower part a firm coagulum of blood, of about the size of a French olive. It accurately closed the opening at the base of the carotid, and it was this which afforded the resistance to the probe and injection of water passing upward from the arteria innominata. The coats of the artery surrounding the coagulum were thickened to about four times their natural size, and lined by a thin layer of fibrine. Above the coagulum, the coats of the artery were thickened to the extent of at least six times their natural size, and, in addition to a layer of fibrine closely adherent to the inner surface of the artery, and continuous with that surrounding the coagulum at the lower part of the tumor, there were three other layers of coagulated lymph. —At the upper part of the thickened portion of the artery, and just above the omo-hyoideus, where the ligature had been applied, was an ulcerated opening on the anterior and tracheal surface of the carotid artery, a quarter of an inch in length, and rather less in breadth, covered by a coagulum

of dark-coloured lymph, communicating with the opening in the integuments." This case, according to my judgment, must be received as another proof that Brasdor's method is capable of producing those changes in the tumor, artery, and circulation, which, if not succeeded by some accidental untoward occurrence, like the ulceration, leading in this case to fatal hemorrhage, may bring about the perfect cure of the disease.

If any doubt remained of this fact after the cases already cited, it would be dispelled by the results of some other trials of the practice, and more particularly by the history of the case of Mary Covis, aged thirty-six, on whom Dr. Bush operated, under very trying and difficult circumstances, with complete success. (*Lancet*, vol. i. 1828.) The tumor extended from the clavicle, on the right side, upwards nearly to the os-hyoideus, pressing the trachea towards the opposite side, and passing under the sterno-mastoid muscle, to nearly an inch beyond its outer border. For nine days previously to the operation, the patient had not been able to swallow anything; her respiration was alarmingly obstructed, and her voice nearly lost. In the operation, the artery immediately above the aneurism was found dilated, not more than half an inch of its extremity being sound, and on this a single silk ligature was placed. As soon as the artery was tied, the tumor became softer and less prominent; and though she had not swallowed anything for nine days, she took, before the wound was dressed, about ten ounces of wine and water. The operation was performed September 11th, 1827. April 19th, 1828, the woman was in perfect health. There was then scarcely a remnant of the tumor; the inordinate action of the heart had ceased; and respiration and deglutition were natural. The facts recorded seem to Mr. Wardrop to prove, that the future growth of an aneurismal tumor may be arrested, and the disease cured, by placing a ligature on the distal side of the sac, especially if no branch of the artery intervene between the sac and the ligature; for, if a considerable branch, and one that afterwards enlarged sufficiently, were to be in this situation, the operation would have little or no effect in producing any diminution of the impetus of the blood in the aneurism, from the cavity of which the blood would pass as freely into the enlarged branch, as it previously did along the trunk itself. Hence we see why Brasdor's operation will probably be attended with greater success on carotid than other aneurisms, the common carotid artery giving off in its course no branches which would interfere with the principles of the practice. Of five operations of this description, which had been performed on the carotid artery at the period when M. Lisfranc published on aneurism, three were completely successful; and of the other two, one performed by Mr. Wardrop in December, 1826, and the other by Mr. Montgomery, at the Mauritius, in 1829, the particulars leave doubts whether in one instance, the carotid artery had been tied, and whether the case was a carotid aneurism; and whether, in the other, the disease had not been an aneurism of the arch of the aorta. (See *De l'Oblitération des Artères*, p. 100, 150; and *Dupuytren, Clin. Chir.* t. iv. p. 593.)

Mr. Wardrop himself regards Brasdor's operation as not merely applicable to examples, in which it is impracticable to place a ligature on the

cardiac side of the sac, but as likely to merit the preference when the tumor is large, and likely to inflame after the circulation through the sac is interrupted. This inference he makes from the fact of the immediate diminution of the swelling, which has usually followed the application of the ligature on the distal side of the aneurism. He also deems it probable that, in this method, there is less risk of hemorrhage from the part of the vessel on which the ligature is applied, than in the Hunterian operation. On the principle that it is sufficient for the cure of an aneurism, that the impetus of the blood through it be diminished, as the deposit of lamellated coagula within the sac will then increase, Mr. Wardrop urges the propriety of extending Brasdor's method to aneurisms of the arteria innominata; but the very interesting and valuable cases which are adduced in confirmation of his views of these particular aneurisms, will be more conveniently noticed in the sequel, where reference also will be made to some instances in which Brasdor's operation was practised for the cure of inguinal and subclavian aneurisms. As an admirer of the improvement of surgery, I must not quit this part of the subject, without expressing the conviction that I entertain of the service which Mr. Wardrop has rendered the profession and the public by his able and enlightened view of a valuable operation, which, without his exertions and example, might long have remained quite neglected, or briefly mentioned in the history of surgery as a dangerous proceeding, unworthy of further trials.

That Brasdor's operation must sometimes fail, and particularly that it should have failed in the trials made of it by Deschamps, Sir A. Cooper, and Mr. Anthony White (see *Guthrie, On Dis. of Arteries*, p. 90) is not surprising. All these cases were inguinal aneurisms; and it does not follow because the method will answer in carotid aneurisms that it will answer in aneurisms in every other situation. I should say, indeed, that unless it retard in a certain degree, the circulation through the sac, or bring on considerable and deep inflammation of the parts, it will never answer in any case; and how much the first of these occurrences must depend upon the existence, or not, of one or more branches between the sac and the ligature, is completely obvious. It is no trivial consideration in favour of this method, that it had the approbation of the celebrated Dupuytren, who observes, that it is the only resource when an aneurism, situated too near the centre of the circulation, continues to increase, notwithstanding debilitating treatment and cold applications. As for the operations performed by Deschamps and Sir Astley Cooper, he expresses his conviction that their failure was owing to the origin of some important branch between the ligature and the aneurismal sac. When, however, no branch, capable of maintaining the circulation in the sac, is situated between this and the ligature, Dupuytren joins Wardrop, and others, in representing the probabilities of a cure as very great. The result, he adds, may also be favourable, although a few small branches may originate near the aneurism, because the coagulum, which is formed in the sac and internal trunk, will be likely to extend into them. But, says he, the presence of considerable branches, such as are capable of impeding the blood in the tumor from assuming a solid consistence, must

evidently render the operation useless. Nay, what is worse, it may accelerate the fatal progress of the disease; because, when the blood has only a narrow outlet on the distal side of the aneurism, nature will make a perpetual effort to enlarge it, and in this progress the sac will be more and more distended. (*Dupuytren, Clin. Chir.* t. iv. p. 592.) The example in which this eminent surgeon tried this practice on the axillary artery will be presently noticed. The fact of the general failure of Brasdor's operation when any considerable vessels arise from the sac, or artery, on the cardiac side of the ligature, and the greater success that has attended such operations when performed for carotid aneurism than any other form of this disease, seem to me to justify the view of the principles on which this operation sometimes brings about a cure, entertained by Hodgson, Wardrop, and Dupuytren. I make this remark, fully aware of the suggestion of Mr. Guthrie, that the cure, so far as it goes, is affected by inflammation of the artery and sac, and not by the mere coagulation of the blood in them. (See *Guthrie, On Dis. of the Arteries*, p. 179.) He also enters into an inquiry how far the communicating of inflammation to an aneurism so near the heart as an aneurism of the innominata or lower part of the carotid, is an advisable proceeding. He argues, that too much inflammation kills the patient, while too little is insufficient to effect a cure. In support of his reasoning, Mr. Guthrie takes a different view of Mr. Montgomery's case from what that gentleman himself does; and on the following grounds:—"An aneurismal sac, of the size described in the first part of the case, never could disappear in four months by any of the processes of nature, or after any operation performed for its cure, with which we are at present acquainted; more particularly as the remains of the artery and vein were discoverable, although obliterated, by which I understand them to have become impervious. *There never was then an aneurism of the carotid*; but the aneurism, which was found to exist between the origin of the left carotid and the innominata, had formerly extended up the neck, so as to resemble an aneurism of the carotid. The operation on the carotid gave rise to inflammation, which extended first to the arch of the aorta, and to the aneurismal sac, and afterwards along the aorta to the heart and pericardium, which, in the end, destroyed the patient." (See *Guthrie, On Dis. of Arteries*, p. 198.) Whatever may have really happened in this instance, it will not form an adequate ground for the rejection of Brasdor's operation in examples where the aneurism is truly one of the carotid, and a ligature cannot be applied below the tumor. Indeed, M. Lisfranc argues, that Mr. Guthrie's objection of the inflammation being likely to be propagated to the heart, has no weight at all; for, says he, "If this consequence is so greatly dreaded after the ligature is placed on the distal side of the sac, how much more so must it be, when Anel's method is pursued! Besides, is the fear of such inflammation, which is after all very uncertain, a sufficient reason for renouncing the only hope of saving the patient?" (*Lisfranc, De l'Oblitération des Artères*, p. 97.)

In this article I have not yet mentioned the proposal made by Dr. Jameson, of Baltimore, to substitute for the ligature a seton composed of thread, or of a piece of doe-skin. The carotid of

a sheep was transfixed with a needle, armed with a slip of doe-skin of a conical shape, three lines broad at its greatest extremity. The two ends of it were cut off three lines from the vessel. There was no hemorrhage during the operation. The animal was killed on the twenty-second day; and the coats of the artery were found considerably thickened for an inch above and below the seton. On one side of the vessel there was no trace of the wound; but, on the other, there was a slight depression, containing a yellowish substance, which proved to be a small particle of doe-skin. The parietes of the artery were in contact, and every where united, excepting a flattened aperture, capable of admitting a small probe. The same experiment was repeated on the carotids of dogs by Dr. Jameson, and also by M. Worms, at the Val de Grace, in Paris, with similar results. M. Amussat varied the process by puncturing the artery with a curved needle, armed with a common thread, which was conveyed up within the tube of the vessel about an inch, and then brought out through the side of the vessel, by means of the needle. Then the ligature was drawn further up, till its lower end was entirely within the artery. A knot was next made near the vessel, and the rest of the ligature cut off. In small arteries, a clot was produced round the thread, and the artery became obliterated. In vessels above a certain size, no clot was found.

With respect to setons, as substitutes for the ligature in the treatment of aneurism, I am of opinion that they promise no advantage whatsoever, and as being less likely to produce the desired obliteration of the artery, should never be employed on the human subject. I entertain the same opinion of acupuncture, which has been tried by M. Velpeau, M. Amussat, and Mr. Benjamin Phillips, on the arteries of animals. In some of these experiments, one or more needles or pins were thrust through the arteries without any preliminary exposure of these vessels; while, in others, the arteries were first laid bare. The accounts given of these experiments prove, that the obliteration of the vessel by the plan is a matter of great uncertainty; and that in several instances, where the attempt was made to transfix the artery through the undivided coverings, either it was not hit at all, or only pierced very near one of its sides. (*Lisfranc, De l'Obliteration des Artères*, p. 77; also *Mr. B. Phillips, On the Cure of Aneurismal Tumors without the Knife or Ligature*.) Besides, it is doubtful whether the arteries of the human body can be so easily rendered impervious, or the process of reparation be so favourably carried on in them, as in the arteries of animals. As Mr. Guthrie observes, it is probable that a simple puncture with a needle would sometimes heal; but he has seen two instances, "in which the femoral artery was wounded with a tenaculum, and ulceration followed by hemorrhage, took place in both, requiring application of a ligature." (See *Guthrie, On Dis. of Arteries*, p. 212.)

I shall finish these general observations on the treatment of external aneurisms, or such as admit more particularly of surgical treatment, with observing, that, in England, surgeons now lose few patients either from gangrene of the limb or secondary hemorrhage; and this, notwithstanding they may sometimes prefer applying a ligature above the profunda to cutting open the aneurismal tumor. I firmly believe, that such matchless

success is to be ascribed to the perfection in their mode of operating; the choice of a proper kind of ligature; the right plan of applying it; the rejection of the employment of several ligatures at a time; the great care taken to promote the healing of the wound as quickly as possible; the avoidance of all unnecessary and hurtful extraneous substances in the wound; and, above all, the relinquishment of the formidable proceeding of cutting open the tumor.

In the consideration of particular aneurisms, I shall begin with those which may be cured by a surgical operation; and here we shall be fully satisfied that "*l'art de guérir ne triomphe jamais plus heureusement que lorsqu'il peut employer la médecine efficace, c'est à dire, les moyens chirurgicaux ou opératoires.*" (*Pelletan, Clinique Chir.* t. i. p. 110.)

OF POPLITEAL ANEURISM, AND OPERATION FOR ITS CURE.

Notwithstanding the solitary example in which M. A. Severinus, early in the 17th century, tied the femoral artery near Poupart's ligament in a case of aneurism (*De Efficac. Méd.* lib. i. p. 2, c. 51), the practice of tying arteries wounded either by accident or in the performance of surgical operations, and even the plan of tying the brachial artery for the cure of aneurism at the bend of the arm, were known long before the operation for the relief of popliteal aneurism was attempted. The considerable size of the femoral artery, its deep situation, the urgent symptoms of the disease, and ignorance of the resources of nature for transmitting blood into the limb after the ligature of the vessel, are the circumstances which appear to have deterred former surgeons from this operation.

Valsalva treated popliteal aneurisms on the debilitating method, and published one or two equivocal proofs of its success. In Pelletan's first memoir on aneurism, and in the 3rd vol. of Sabatier's *Médecine Opératoire*, as I shall hereafter notice again, are two cases of axillary aneurisms, which were cured by Valsalva's treatment. But encouraging as such examples may be, experience is not yet sufficiently favourable to this practice to allow it to bear a comparison, in point of efficacy, with the surgical operation, or to justify the general rejection of this last more certain means of cure. As Pelletan admits, Valsalva's treatment is extremely severe; the event of it doubtful; and were the plan to fail, the patient might not be left in a condition to bear an operation, for the success of which it seems necessary that a certain strength of vascular action should exist, in order that the blood may be freely transmitted through such arterial branches as are to supply the places of the main trunk after it has been tied. The time, therefore, has not yet arrived when surgical operations for the relief of aneurisms can be relinquished. (*Clinique Chir.* t. i. p. 114.)

[Femoral and popliteal aneurisms may usually be successfully treated by the compression of the artery in the groin, by means of Carte's compressor, or some similar instrument applied in accordance with the principles already laid down. In no cases of aneurism is compression so serviceable as in these, and it should, as a general rule, be had recourse to in the first instance. In the event of its failing from some untoward accident,

the ligature of the femoral artery may then be undertaken.]

Aneurisms in general, and, among them, the popliteal case, are all attended with some little chance of a spontaneous cure; yet this desirable event is too uncommon to be a judicious reason for postponing the operation, especially as it is the usual course of the disease to continue to increase; while, in the early stage, the cure may be more speedily accomplished. In fact, when the patient is not too much debilitated, the experience of modern operators leaves no ground for apprehending that the anastomoses will not suffice for the due nourishment of the leg, and consequently proves, that waiting beyond a certain time for the enlargement of the collateral vessels to take place is altogether an unnecessary and a disadvantageous method. Popliteal aneurisms, as well as other external tumors of the same nature, stand some chance of a spontaneous cure, when any cause induces a general, violent, and deep inflammation all over the swelling; for, then the communication between the sac and the artery is likely to become closed with coagulating lymph, and the pulsation of the tumor to be suddenly and permanently stopped. If, in this state, the disease sloughs, and the patient's constitution holds out, the coagulated blood in the sac and the sloughs are gradually detached, leaving a deep ulcer, which ultimately heals. An example, in which a popliteal aneurism was cured by such a process, is related in the *Trans. for the Improvement of Med. and Chir. Knowledge*, vol. ii. p. 268.

In former times, when all hopes of curing a popliteal aneurism by Valsalva's method, by compression, or a natural process, were at an end, amputation of the limb was considered as the sole and necessary means of saving the patient's life. But, about seventy years ago, the confidence of surgeons in the sufficiency of the anastomosing vessels for the continuance of the circulation began to increase; and, in opposition to the tenets of J. L. Petit and Pott, experience soon proved, that, in general, not only might the patient's life be saved, but his limb also, and this without any operation that could be compared with amputation, in regard to severity. On looking back to the history of amputation, we shall find that A. N. Guenault was one of the earliest writers who disapproved of amputation as not truly necessary in cases of popliteal aneurism.

It is alleged that Teislere, Molinelli, Guattani, Mazotti, and some other celebrated Italian surgeons, were the first who ventured to tie the popliteal artery for the cure of aneurism. The path, as Pelletan remarks, had been pointed out to them by Winslow and Haller, whose valuable descriptions and plates of the arterial anastomoses about the knee-joint, showed by what means the lower part of the limb would be nourished, after a ligature had been placed on the principal arterial trunk. For almost thirty years, however, the practice of tying the popliteal artery was confined to the Italian surgeons. Pelletan believes that he was the first who attempted such an operation at Paris, nearly thirty years ago (alluding to about the year 1780, the *Clinique Chirurgicale* being dated 1810).

However, this operation of opening the tumor and tying the popliteal artery itself, was a severe and often a fatal proceeding, and does not admit of

being compared with the Hunterian operation, in point either of simplicity, safety, or success, as I shall explain, after the detail of a few particulars relating to the popliteal aneurism.

On whatsoever side of the artery the tumor is produced, it can be plainly felt in the hollow between the hamstrings, and in general its nature is as easily ascertained by the pulsation in every part of it. In the early stage of spontaneous aneurism, the swelling is soft, not usually accompanied by pain, and capable of being lessened by pressure, and more particularly by compression of the artery above the tumour, whereby the flow of blood into it is stopped, or materially diminished. The pulsation then ceases, but is restored on the compression being removed; and with the return of the pulsation, and that of the swelling to its original size, a peculiar thrilling feel is experienced, arising from the passage of the blood into the aneurism again from the artery, and termed by the French *bruissement*, because attended with a confused rattling sound. After the swelling has existed a little while, the *bruit de soufflet*, or bellows sound, is likewise more audible, especially when the stethoscope is employed. At length the tumor becomes firmer, and the blood cannot be entirely pressed out of it, because the interior of the sac is now more or less covered by solid lamellated blood. The patient, in order to avoid bearing much on the affected limb, limps in the early stage of the case; but, "as the aneurism increases, he does so from two causes—the pressure which takes place on the nerves passing to the toes, and which gives rise to pain, not in the part affected, but in that to which the terminations of the nerves are distributed; and, from the same cause, giving rise to contraction of the muscles and rigidity of the tendons passing behind the joint, the leg is permanently bent; the toes and leg are extremely painful; and the foot and leg, incapable of bearing the weight of the body, become swelled and cedematous." (See *Guthrie, On Dis. of the Arteries*, t. i. p. 109.) Sometimes, however, the patient, even in the spontaneous form of the disease, does complain of great pain in the ham, and of numbness in the leg and foot, instead of pain in those parts. (See *Case by Collis, in Dublin Journ. of Med. Sci.*, vol. v. p. 33.) The symptoms of a popliteal aneurism, as they present themselves, when the sac gives way under the integuments and fascia, or under the heads of the gastrocnemius, I need not repeat as they have been noticed in the general observations on aneurism. The progress of a popliteal aneurism differs in different examples; being sometimes slow, in other instances rapid. Mr. Collis had a patient with an aneurism in each ham, and the disease continued almost stationary from 1818 to 1833, during all which time so little inconvenience was experienced by the patient, that he was able to discharge the fatiguing duties of an infantry soldier. (See *Dublin Journ. of Med. Science*, vol. v. p. 32.) I had a patient with popliteal aneurism, who, in his business of an organ-builder, used to ascend ladders, and lead a very active life for a considerable length of time; indeed, until the sac gave way, and the disease changed into the diffused form. (See *Med. Chir. Trans.* vol. xvi.) Though the disease may not occur in the popliteal artery so often as in the aorta itself, it certainly is seen more frequently in the former vessel than any other branch derived from the aorta. As Sir E.

Home has observed, this circumstance has never been satisfactorily explained; and, what is rather curious, in many instances of this disease, the patients have been coachmen and postillions. Morgagni found aneurisms of the aorta most frequent in guides, post-boys, and other persons who sit almost continually on horseback; a fact, which he imputes to the concussion and agitation to which such persons are exposed. Some allusion to this subject has already been made in the foregoing pages. Whether an explanation of the frequency of popliteal aneurisms can be correctly referred to the force with which the blood must be impelled against the bend of the artery when the knee is in a state of flexion, seems questionable, though it is on a similar principle that the great frequency of aneurisms of the curvature of the aorta is attempted to be solved. (*Home, in Trans. for the Improvement of Med. and Chir. Knowledge*, vol. i. &c.; and *Monro, in Ed. Med. Essays*, vol. v.) Were this the only, or even the principal cause, surely one would have reason to expect aneurisms to be at least as frequent in the axilla, and in the bend of the elbow, as in the ham.

Popliteal aneurism was once supposed to arise from a weakness in the coats of the artery, independently of disease. If this were true, we might reasonably conclude, that, except, at the dilated part, the vessel would be sound. Then the old practice of opening the sac, tying the artery above and below it, and leaving the bag to suppurate and heal up, would naturally present itself. As the arterial coats were found to be altered in structure higher up than the tumor and the artery immediately above the sac, seldom united when tied, but, when the ligature came away, the patient was destroyed by hemorrhage, Mr. Hunter concluded, that some disease affected the coats of the vessel, before the actual occurrence of aneurism. Dissatisfied with Haller's experiments on frogs, showing that weakness alone could give rise to aneurism, he tried what would happen in a quadruped, whose vessels were very similar in structure to the human. Having denuded above an inch of the carotid artery of a dog, and removed its external coat, he dissected off the other coats, layer after layer, till what remained was so thin, that the blood could be seen through it. In about three weeks the dog was killed, when the wound was found closed over the artery, which was neither increased, nor diminished in size.

It being conjectured that the prevention of aneurism, perhaps, arose from the parts being immediately laid down on the weakened portion of the artery, Sir E. Home stripped off the outer layers of the femoral artery of a dog, placed lint over the exposed part of the vessel to keep it from uniting to the sides of the wound, and in six weeks killed the animal, and injected the artery, which was neither enlarged nor diminished, its coats having regained their natural thickness and appearance.

These experiments strengthened Mr. Hunter's belief, that aneurismal arteries are diseased; that the morbid affection frequently extends a good way from the sac along the vessel; and that the cause of failure, in the old operation, arose from tying a diseased artery, which was incapable of uniting before the ligature separated. These reflections led him to propose taking up the artery in the anterior part of the thigh, at some distance

from the diseased portion, so as to diminish the risk of hemorrhage, and be enabled to get at the vessel again, in case it should bleed. The stream of blood into the sac being stopped, he concluded that the sac and its contents would be absorbed, and the tumor gradually disappear, so as to render any opening of it unnecessary.

The first operation of this kind ever done was performed on a coachman, by Mr. Hunter, in St. George's Hospital, December, 1785. An incision was made on the anterior and inner part of the thigh, rather below its middle, which wound was continued obliquely across the inner edge of the sartorius muscle, and made large, in order to facilitate the performance of whatever might be necessary. The fascia covering the artery was then laid bare, for about three inches, after which the vessel itself could be felt. A cut, about an inch long, was then made through the fascia, along the side of the artery, and the fascia dissected off. Thus the vessel was exposed. Having disengaged it from its connections by means of the knife and a thin spatula, Mr. Hunter put a double ligature under it with an eye-probe. The double ligature was then cut, so as to make two separate ones. The artery was now tied with both these ligatures, but *so slightly as only to compress the sides together*. Two additional ligatures were similarly applied a little lower, with a view of compressing some length of artery so as to make amends for the want of tightness, as it was wished to avoid great pressure on any one part of the vessel. The ligatures were left hanging out of the wound, which was closed with sticking-plaster. On the second day the aneurism had lost one third of its size, and, on the fourth, the wound was every where healed, except where the ligatures were situated. On the ninth, there was a considerable discharge of blood from the apertures of the ligatures, but it ceased on applying a tourniquet, and did not recur. On the fifteenth day after the operation, some of the ligatures came away, followed by a small quantity of matter; and about the latter end of January, 1786, the man went out of the hospital, the tumor having become still less. In the course of the spring, abscesses in the vicinity of the cicatrix followed, and some pieces of ligature were occasionally discharged. In the beginning of July, a piece of ligature, about one inch long, came away, after which the swelling went off entirely, and the man left the hospital again on the 8th perfectly well, there being no appearance of swelling in the ham. This subject died of a fever in March, 1787, and on dissection, the femoral artery was found impervious from the giving off of the arteria profunda down to the place of the ligature, and an ossification had taken place for an inch and a half along the course of this part of the vessel. Below this portion the vessel was pervious, till just before it came to the aneurismal sac, where it was again closed. What remained of the sac was somewhat larger than a hen's egg, and its communication with the popliteal artery was obliterated. The rest of the particulars of the dissection are very interesting. (*See Trans. for the Improvement of Med. and Chir. Knowledge*, vol. i. p. 153.)

This celebrated case completely established the important fact, that simply taking off the force of the circulation is sufficient to cure an aneurism,

the tumor being afterwards diminished and removed by the action of the absorbent vessels. In order to confirm the same fact, Sir E. Home related a case of femoral aneurism, which got well without an operation, but on a similar principle to what occurs when the artery is tied. A trial of pressure had been made without avail. The tumor became very large, and such inflammation took place in the sac and integuments, that mortification was impending; no pulsation could now be felt in the tumor, or the artery above it. The correct inference of Sir E. Home was, that a coagulum, which we know always occurs in an artery previously to mortification, seemingly to prevent bleeding, had formed in this instance, and, in conjunction with the effusion of coagulable lymph about the root of the aneurism, had kept the blood from entering the sac.

Mr. Hunter's second operation was on a trooper. Instead of using several ligatures, which were found hurtful, he tied the artery and vein with a single strong one; but, unluckily, the experiment was made of dressing the wound from the bottom, instead of attempting to unite it at once, and the result was, that the man died of hemorrhage.

After this case, Mr. Hunter's practice was to tie the artery alone with one strong ligature, and unite the wound as speedily as possible.

Having recorded Mr. Hunter's cases, which first established the present method of operating for the cure of popliteal aneurisms, I shall not repeat the strong reasons which exist against the employment of reserve-ligatures; metallic compressors; two ligatures, with the division of the vessel between them; the interposition of pieces of linen, wood, cork, agaric, &c. between the knot and the vessel; the use of large ligatures; and other contrivances, the merits, or rather demerits, of which have been already fully considered in the preceding section. My next duty is to explain the method of performing the Hunterian operation, as brought to its modern state of improvement, and adapted to the wise principles which first emanated from the valuable experiments and investigations of Dr. Jones. (See HEMORRHAGE.)

In the arrangement of the assistants, one of them should be so placed, that, if required, in consequence of any accidental wound of that vessel in the operation, he can compress the femoral artery as it passes over the brim of the pelvis; but, as Scarpa justly observes, no pressure of this kind is to be made, unless the accident referred to should happen, because the pulsations of the artery, inasmuch as they indicate the track of the vessel, must tend materially to facilitate the operation. The surgeon is to explore with his forefinger the course of the artery from the crural arch downwards; and when he comes to the place where the vibration of this vessel begins to be less distinctly felt, this point is to be fixed upon for the lower end of the external incision. This angle of the wound will fall nearly on the inner edge of the sartorius, just where this muscle crosses the track of the femoral artery, and at the very apex of the triangle formed by the convergence of the triceps and vastus internus. A little more than three inches above the place here fixed upon, the surgeon is to begin, with a convex-edged bistoury, the incision through the integuments and cellular substance, and carry the wound down the thigh, in a slightly oblique line,

from without inwards, so as to make it follow the course of the artery, as far as the apex of the above-mentioned triangular space, or the point where the vessel passes under the inner edge of the sartorius muscle. In order to make this first external incision with correctness, I consider it a good rule always to take particular notice of the line described by the sartorius on the thigh, the inner margin of which muscle, at the place where it meets the artery, as we have seen, forms at once the lower boundary of the incision, and an important guide to the vessel itself. By observing the track of the sartorius attentively, we shall likewise avoid all chance of making the wound too low down, so as to have this muscle intervening between the incision and the artery; a greater source of embarrassment in the operation, and of troublesome consequences afterwards, than, perhaps, any other error; for when this has happened, and the surgeon has not room enough afforded by the higher part of the wound to get at the artery above the sartorius, he is compelled to dissect and raise up this muscle from its natural connections, ere he can plainly discover the vessel. This inconvenience made a deep impression on me in the first case where I tied the femoral artery; for the intervention of the sartorius in a stout soldier, upon whom the operation was done, threw me into the dilemma of either dissecting at the outer edge of this muscle, and drawing it inwards, or of enlarging the wound upwards. The latter proceeding was that to which I gave the preference, because it seemed to me an excellent maxim in this operation, to avoid making any further detachment of parts from their natural connections than is absolutely necessary; and I knew, that when the wound was extended a little higher up, the artery would present itself more superficially, quite unconcealed by any muscle whatever. In fact, in the superior third of the thigh, the anterior surface of the artery is covered only by the common integuments, the superficial fascia, the inguinal glands, the fascia lata, a little cellular tissue, and the arterial sheath. But in the middle third of the limb the vessel is more deeply seated, as, in addition to the skin, superficial fascia, fascia lata, cellular tissue, and arterial sheath, it is covered by the sartorius muscle, beneath which is a fascia composed of oblique fibres, passing from the tendon of the adductor longus and magnus muscle to the vastus internus. (See *Dr. Quain's Elements*, p. 506, ed. 2.) This last fascia begins superiorly at the point where the sartorius first passes in front of the artery, and is here thin; but, about the middle of the thigh, it is very dense. It terminates at the upper part of the inferior third of the thigh, in a well-defined edge, beneath which passes the nervus saphænus major. If this fascia be divided the femoral artery and vein will be exposed. (See *Harrison's Surgical Anatomy of the Arteries*, vol. ii. p. 136, ed. 2.) Anatomy teaches us, then, that the femoral artery may be more readily taken up in the superior third of the thigh than in the middle. Strongly, therefore, as my principles lead me to condemn Scarpa's modification of the ligature, his use of from four to six threads, and his interposition of a roll of linen between the knot and the vessel, I feel pleasure in expressing my conviction of one excellence in his mode of operating; an improvement which is now obtaining,

if it has not already obtained, the universal approbation of the surgical profession. This amendment consists in making the incision in the upper third of the thigh, or a little higher than the place where Mr. Hunter used to make the wound. Scarpa's reason for this practice is to avoid the necessity of removing the sartorius muscle too much from its position, or of turning it back, to bring the artery into view, so as to be tied. I have seen the best operators, even professors of anatomy, embarrassed, by having the sartorius muscle immediately in their way after the first incision; and as the vessel is more superficial a little higher up, not being covered there by the sartorius, or the dense fascia extended from the adductor muscle to the vastus internus lower down the thigh, while the place is further from the diseased part of the artery, and there is no hazard of the anastomoses failing to keep up the circulation, this part of Scarpa's practice is highly deserving of imitation.

"The part of the limb (observes Mr. Hodgson) in which the femoral artery can be tied with the greatest facility, is between four and five inches below Poupart's ligament. The profunda generally arises from the femoral artery an inch and a half, or an inch and three quarters, below Poupart's ligament: it very rarely arises so low as two inches. If, therefore, the ligature be applied to the femoral artery at the distance of four or five inches below Poupart's ligament, the surgeon will not be embarrassed by meeting with the profunda during the operation, and the chance of causing secondary hemorrhage, by tying the artery close to the origin of this vessel, will be obviated." (*On the Dis. of Arteries, &c.* p. 434.)

With the view of preventing injury of the femoral vein, Mr. Carmichael recommended a plan, which is now always followed, namely, that of introducing the needle on the pubic side of the artery, where the vein presents itself to view, and can be most easily avoided. He remarks, that the only part of the thigh, from Poupart's ligament to the tendon of the adductor magnus, in which the femoral vein is not completely covered by the artery, lies within the space which extends from Poupart's ligament to the point where the artery meets the sartorius muscle. At the part of this space most distant from Poupart's ligament, the vein begins to disclose itself at the pubic side of the artery, from beneath which it emerges more and more as it ascends. (*See Trans. &c. of the Fellows, &c. of the King's and Queen's College of Physicians, Ireland, vol. ii. p. 357.*)

[Wound of the femoral vein is without doubt the most serious accident that can happen in the operation for ligature of the superficial femoral artery, and is one of which there is especial risk when this operation is had recourse to for aneurism, as in this disease the fine cellular tissue which naturally connects the two vessels often becomes thickened and indurated, in consequence of inflammatory action having extended upwards from the sac to the sheath of the vessels. It is best avoided by passing the needle in the way that has been already recommended, unarmed, and without the employment of force. This accident is almost invariably fatal, there being but very few instances on record in which patients have survived it; death usually resulting from diffuse phlebitis, or the supervention of gangrene. The true cause of the fatal result in these cases was first pointed out

by Mr. Hadwen, who showed that when the vein is wounded by the aneurismal needle, it is transfixed at two points, between which the thread is drawn across; and when this is tied, a segment of the vein is necessarily included with the artery in the noose. It is this inclusion of the ligature within a portion of the vein, where it acts like a seton, and keeps up constant irritation, that prevents the occurrence of adhesive phlebitis, and occasions diffuse inflammation in the interior of the vessel; and it is consequently this circumstance, and not the mere wound of the vein, that determines the great fatality of this peculiar accident. Guided by this view of the mechanism of the injury, the indications in its treatment become obvious. They consist in removing the ligature at once, and thus, by taking away the main source of irritation, converting the wound into a simple puncture of the vessel, which readily assumes adhesive action. The surgeon should therefore, as soon as the accident is perceived, withdraw the ligature, and opening the sheath about half an inch higher up, reapply it to the artery there. The hemorrhage from the punctured vein readily ceases on the application of a compress.]

The femoral vein, in a few rare instances, has been found double. Thus, in the case recorded by Mr. Macready, the popliteal vein, in the lower part of the popliteal space, "consisted of but one trunk, as usual, and held its natural situation, with respect to the surrounding parts; but in the upper third of the popliteal space, it divided into two branches, which passed off at an acute angle, having one of the muscular branches supplied by the popliteal artery in the apex of the angle. The veins then ascended; one, the internal and posterior, holding its usual position, with respect to the artery, namely, posterior to it at first, but getting internal as it ascended; the other branch crossed the artery, and ascended anteriorly, and a little externally to it, which relation it held until it arrived at the upper third of Scarpa's space, where it crossed the artery again, and then, uniting with the internal, formed the femoral, which appeared dilated into a sinus. The vein then had the usual relation to the artery, but was somewhat larger." (*Macready, in Dublin Journ. of Med. Science, vol. ix. p. 318.*) In the same volume, p. 325, Mr. Goodall has recorded another example of double femoral vein. In the latter, the external branch crossed the artery twice. This occasional variety in the femoral vein is important, in relation to the operation for popliteal aneurism.

The skin and superficial fascia are to be divided, in the situation and to the extent above specified, down to the femoral fascia, under which the artery lies, and may be felt beating. The next object, therefore, is to divide the fascia, which is here much thinner than at the outer side of the limb, and may be cut with another stroke of the bistoury; or, (what is safer, with the view of abstaining from all chance of wounding the artery,) a slight cut may first be made in the fascia, the division of which may then be made to the requisite extent by introducing under it a grooved director, on which the further incision may be made with perfect security. The fascia is to be divided in the direction of the external wound, but, to what extent, is a point on which surgical writers differ, and, indeed, they must here differ, so long as they are not unanimous about the me-

thod of applying the ligature round the artery ; because, if it be intended to use a broad ligature, with a cylindrical piece of linen interposed between it and the artery, or especially if it be designed to apply two ligatures and divide the vessel in the interspace, more of the artery must be exposed, and of course more of the fascia must be cut, than when it is simply meant to surround the vessel with a single small ligature. Such operators also as have contracted the pernicious habit of insulating the artery all round sufficiently far to let them thrust their fingers under it, will likewise require an extensive opening in the fascia. This detachment of the vessel for an inch or more, for the purpose of placing the finger under it, is a measure which deserves to be condemned in the strongest terms, as it is the very thing which produces some risk of injuring the saphena vein, and has a tendency to bring on secondary hemorrhage, inasmuch as it occasions unnecessary handling, stretching, and disturbance of the artery and surrounding parts, and an inevitable division of the vessels, by which the arterial coats are supplied with blood.

I shall suppose the fascia has now been divided, under which the surgeon distinctly feels the pulsations of the femoral artery, which is still invested by the cellular sheath. The femoral vein lies directly under this vessel, the nervus saphænus major, runs for some way upon the sheath of the vessels, and then penetrates it so as to get into contact with the anterior and external side of the vessel in the middle third of the thigh, care should be taken not to include it in the ligature. The next object, therefore, is to pass a single ligature round the artery, without including, or in any manner meddling with, the subjacent femoral vein, or detaching and disturbing the artery. For this purpose, the best direction is that given by my friend Mr. Lawrence, especially when combined with Mr. Carmichael's plan of letting the needle be introduced on the pubic side of the artery. "After dissecting down to the artery, a slight scratch or incision may be made through the sheath close to the side of the vessel. Then, with a narrow aneurism needle, nearly pointed at the end, and made as thin at its edge as it can be without cutting, a single silk ligature is to be conveyed round it, the point of the needle being kept in contact with the artery. A needle of this form makes its way easily through the cellular substance, and the vessel is detached only in the track of the instrument." (See *Med. Chir. Trans.* vol. iv.)

Dupuyrent and several other eminent French surgeons first pass a bent director under the artery, and then, by means of an eye-probe, which is pushed along the groove, convey the ligature under the vessel. This is an eligible method, when it is particularly desirable to see, before the ligature is passed, that nothing is raised but the artery itself.

Of the kind of ligature to be employed, I need only say here, that it should be a single one, composed of firm materials, in order to avoid the necessity for increasing its diameter more than would be desirable for reasons elsewhere considered. (See HEMORRHAGE and LIGATURE.) The ligature having been put under the artery, one end of it is to be drawn completely through the track made for it by the needle, which instrument is then to be taken away, leaving the ligature under the vessel. The ligature is now to be tied in a steady firm manner, but without any im-

moderate force, which can never be necessary even for the division of the inner coats of the vessel. In this part of the operation, a few practitioners give the preference to what is termed the *surgeon's knot*, and commend this plan of fastening the ligature ; a plan, which consists in putting the end of the cord twice through the noose, before the constriction is made. The only good of the surgeon's knot is, that it does not so readily slip and loosen as a common one ; but Scarpa thinks a simple knot best, as it does not, like the other, prevent the surgeon from calculating the force with which the artery is constricted. (*On Aneurism*, p. 281, ed. 2.) A better reason against the surgeon's knot, is the irregularity with which a ligature in this form will lie round the vessel. A simple noose should therefore be first made and tightened, and then a second one, so as to form a common knot ; and now, as a matter of precaution against the possibility of the ligatures slipping and becoming loose, the surgeon, if he pleases, can tie the knot once again. One end of the ligature is next to be cut off near the knot ; and the sides of the wound are to be brought together with strips of adhesive plaster, or by the interrupted suture. The remaining end of the ligature should always be brought out at the nearest point of the external wound to the knot on the artery.

If by any accident the artery be pricked in the operation, a double ligature should be passed under the vessel, and one part of it tied above, the other below the puncture. Thus, Mr. Collis, in endeavouring to separate the artery from the vein, "made a small opening, about the size of a pin's point, into the artery, from which a rapid jet of blood took place. The artery was immediately compressed against the os pubis, and a double ligature applied, one part of which was tied upon the highest exposed portion of the vessel, and the other upon the lowest, leaving between both about a quarter of an inch of the artery." (See *Dublin Journ. of Med. Science*, vol. v. p. 31.) The case ended favourably, and illustrates what should be done under similar circumstances in other operations for aneurisms. The manner of taking up the femoral artery in the middle third of the thigh, and in the groin, will be described under the head of ARTERIES.

The effects which, in general immediately follow the operation are a total cessation of the pulsation of the aneurismal tumor ; a manifest sinking and flaccidity of the swelling ; a diminution of pain in the seat of the disease ; and a strong vibration of the articular arteries round the knee. As Mr. Hodgson has remarked, the unusual influx of blood into the minute ramifications, when a main artery is suddenly rendered impervious, is generally attended with a remarkable increase in the temperature of the limb. After tying the femoral artery for the cure of popliteal aneurism, the same phenomenon occurs, at least after a short time, during which the temperature of the leg and foot frequently continues lower than that of the sound limb. But, in a few hours, it generally rises, and is sometimes several degrees higher than that of the opposite member. This state lasts several days, at the end of which time, the heat of the limb which had been operated upon will be found to be about the same as that of other parts of the body. (*Hodgson, On Diseases of Arteries, &c.* p. 356.) It is only while the limb is colder than

natural, that it ought ever to be fomented, or covered with flannel. In particular examples, there is no increase of temperature in the limb at any period after the operation; a fact, which Mr. Hodgson refers to the probability of a collateral circulation having already been established, in consequence of the obstruction to the passage of the blood through the main artery by the accumulation of the coagulum in the aneurismal sac. Of course, unless a collateral circulation be established, the operation cannot succeed, as the limb will mortify: it behoves us, therefore, to be aware of the circumstances which may prevent the due transmission of the blood to the inferior part of the limb. These are ably explained and commented upon in Mr. Hodgson's work: 1st, An extensive transverse wound, by which the principal anastomosing branches are divided. 2ndly, Tight bandages and pressure operating so as to obstruct the same vessels. 3rdly, The immense bulk of the tumor, and the pressure upon the principal collateral arteries. 4thly, Calculous depositions in the coats of the arteries of the limb. 5thly, Advanced age. 6thly, A languid state of the circulation; a fact, indicating the wrongness of venesection, as a general practice after the operation, though it may yet be right to adopt this treatment, where the pulsations return in the tumor with unusual strength, and appear to stop the diminution of the swelling. 7thly, The abstraction of heat from the limb by cold evaporating lotions; a plan which can only be right when there is a great increase of heat in the limb, a tendency to inflammation, or a return of strong pulsation in the tumor.

Sir Astley Cooper saw a case, in which the application of white-wash occasioned mortification and the patient's death. In cold weather, he always covers the limb with flannel, or a stocking, and sometimes puts jars filled with hot water to the feet. (See *Lancet*, vol. ii. p. 42.)

If secondary hemorrhage were to occur, ought we to take up the artery higher up, or have recourse to direct pressure on the bleeding point? In one case under Mr. Colles, he applied a compress, pressed down with a screw affixed to an iron hoop about half an inch in breadth, and sufficiently long to encompass the thigh. With this instrument, any degree of pressure could be made on the artery, whilst little or none was made on other parts, and the collateral circulation remained free. The bleeding returned once, but was at length permanently stopped. "My chief object (says Mr. Colles) in recording this case, is to show the advantage to be derived from pressure properly made, in arresting secondary hemorrhage from such a vessel as the femoral artery, and the greater benefit likely to arise from such a mode of proceeding than from tying the artery higher up, which, in the majority of cases in which it has been tried, has failed of saving the life of the patient. (See *Dublin Journ. of Med. Science*, vol. v. p. 36.) Sometimes pressure will answer, and then the ligature of the artery higher up becomes unnecessary; but pressure may not succeed. In an interesting case under Professor Regnoli, the femoral artery was tied in the upper third of the thigh, and secondary hemorrhage took place about a week after the operation. The bleeding was suppressed for a time by pressure on the bleeding point, and the

application of a bladder filled with ice to the wound. The hemorrhage returned, however, and Regnoli decided to take up the external iliac artery. This measure permanently stopped the bleeding; and, *though the artery was so completely ossified, where it was tied, that, on tightening the ligature, a remarkable crepitation was distinctly heard, and it was even apprehended that the ligature had broken the vessel completely through*, the ligature came away on the eighteenth day, without any bleeding. The artery, in fact, had become obliterated. In the end, however, the patient died of gangrene in the leg. (*Istoria, &c. intorno un Aneurisma Popliteo*, Pisa, 1833, p. 26, &c.)

When the operation is done according to the principles laid down in this article, the patient is not too old nor enfeebled, and the after-treatment is properly conducted, mortification cannot be said to be a frequent event. In one case, operated upon by Sir Astley Cooper in 1823, the whole of the foot and part of the leg mortified; but it should be noticed, that in this instance, the whole limb was extremely swollen previously to the artery being taken up. (See *Lancet*, vol. i. p. 436.) In all his extensive practice, he has seen but three or four instances of a failure of the operation from gangrene. (*Lectures, &c.* vol. ii. p. 60.) Mr. Liston has related one example, which he ascribed to the improper use of fomentations with hot salt water. (See *Edinb. Med. Journ.* No. 90, p. 3.) As, however, the patient seems to have been of a very phlogistic diathesis, and to have been attacked with inflammation of other parts, the reality of the alleged cause appears questionable. I have seen but one example of gangrene, and in that only one toe, and a portion of the skin of the instep, sloughed in a very debilitated subject. This partial gangrene of the foot was particularly noticed by Deschamps and Scarpa, the latter of whom regards it as an unusual thing, only likely to happen in old, weak, or unhealthy subjects; and "at any rate (says he), if this should happen in any of these enervated individuals, the patients may console themselves for the loss of one or two of their toes, with the cure of a popliteal aneurism, and the avoidance of a painful and dangerous incision in the ham, and of the tedious suppuration which would have followed it."

Sir Astley Cooper has known retention of urine brought on by the operation in one or two examples, and the use of the catheter indispensable. (*Lectures, &c.* vol. ii. p. 53.) Sir Charles Bell met with a case in which the femoral artery divided below the profunda into two equal branches, the most superficial of which was alone noticed and tied in the operation. The patient died of constitutional disturbance, arising from inflammation in the whole course of the sartorius. After two or three days, the pulsation of the tumor, which had been very strong, ceased in consequence of the coagulation of the blood within the sac; another fact exemplifying that this desirable change will not be prevented by a current of blood being still propelled through the aneurismal cavity. (See *Quarterly Journ.* vol. iii. p. 607.)

Mr. Liston has recorded a case, in which the pulsation and tumor returned several months after the operation. "On consulting with Dr. Thomson, it was agreed to try the effect of methodical bandaging, from the points of the toes upwards, and

a compress over the tumor, with rest, cold applications, and moderate diet." These means had the desired effect; and the patient did not complain much of those pains which so frequently remain after the operation for aneurism.

According to Mr. Liston, these pains are in general distinctly referrible to the sacro-ischiatic nerve and its branches, and are explained by the state of the vessels in the substance of the nerve. In the natural state, the neurilemal vessels, when injected, are not larger than sewing threads; but, when the enlargement of the collateral branches is requisite, owing to the obstruction of the trunk, they also are called on to contribute their share in the new circulation; and they become enormously distended. In one remarkable specimen, in which the limb was injected and examined fifteen years after the superficial femoral artery had been secured for aneurism in the ham, the vessels in the sacro-ischiatic nerve had attained the size of crow-quills, and were convoluted in an extraordinary manner. The pains in the limb, noticed by Mr. Liston as occurring after the operation, he acknowledges, however, are by no means so severe as those experienced previously, and which are produced by the compression and stretching of the nerves by the sac. (*Edinb. Med. Journ.* No. 90, p. 2.)

[The ligature of the femoral artery for popliteal aneurism is, on the whole, a very successful operation. Of 110 cases recorded by Dr. Crisp, only 12 proved fatal; of these 4 died of secondary hemorrhage, and 3 of gangrene of the limb.]

When the operation succeeds, a considerable portion of the artery above the aneurismal tumor is rendered impervious, the vessel indeed being sometimes converted into a solid cord from the origin of the profunda to that of the tibial arteries. (*A. Cooper, Med. Chir. Trans.* vol. ii. p. 254.) In general, however, the obliteration of the artery is less extensive; a fact, particularly noticed in one of Mr. Hunter's cases (*Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge*, vol. i. p. 153), and vainly urged by Deschamps, as a proof of the insufficiency of the new method. (See *Obs. et Réflexions sur la Ligature des principales Artères blessées, et particulièrement sur l'Aneurisme de l'Artère poplitée*, p. 76. Paris, 1797.) It appears from the observations of Mr. Hodgson, that the artery generally becomes impervious, for the space of three or four finger-breadths, at the place where the ligature is applied; below which part its tube is free, and continues so for some distance, when the obliteration again commences, and descends along a considerable extent of the popliteal artery to the origin of the inferior articular or tibial arteries. Thus, says this author, an insulated portion of the femoral artery preserves its cavity, from each extremity of which considerable anastomosing branches arise; the upper branches convey blood into the vessel, and the lower transmit it into anastomosing channels, that originate below the knee. (*On Diseases of Arteries*, &c. p. 278. (Now, as Mr. Hodgson is unacquainted with any case, except that recorded by Sir Astley Cooper, where, after the modern operation, the artery was obliterated from the seat of disease in the ham to the part at which the ligature was applied, he thinks it probable that, in most instances, a double collateral circulation exists in the limb, after this method of cure.

A preparation in the Museum of St. Mary's Hos-

pital, admirably bears out the view here taken by Mr. Hodgson. It was obtained from a patient aged twenty-five, who died of an internal aneurism six months after the ligature had been applied to the femoral artery for the cure of a popliteal aneurism.

In consequence of the motion of the blood being more or less impeded in the aneurismal sac by the application of the ligature to the femoral artery, the aneurismal cavity soon becomes completely filled with coagula, which even block up the adjoining portion of the arterial tube. The coagulated blood in the sac is afterwards absorbed; and a gradual diminution, and final disappearance of the aneurism in the ham ensue; with the exception of a slight induration, which sometimes remains, composed of a remnant of the sac itself, or of the fibrous parts of the blood. This slight hardness in the cavity of the ham occasions no inconvenience, and does not hinder the patient from performing the motions of the knee and leg with quickness and safety. (*Scarpa*, p. 257, edit. 2.)

After the operation, the circulation is carried on principally by the arteria profunda, whose branches communicate with the articular arteries of the popliteal, and with arteries sent to the knee by the anterior and posterior tibial. Large branches in the sciatic nerve, sent off by the arteria profunda, communicate very freely with the popliteal artery, the articular, and branches of the posterior tibial. As Sir Astley Cooper has further explained, the freedom of anastomosis sometimes leads to a reproduction of an aneurism. The femoral artery was tied by Mr. Key, and the patient, after being discharged cured, returned with a painful tumor in the ham, attended with an obscure pulsation. The limb was amputated, and a large artery, passing to the tumor, and situated nearly in the usual place of the femoral, required a ligature. (*Lectures*, &c. vol. ii. p. 60.)

I shall now advert to a few facts in the history of surgery, which eventually led to the bold and successful operations performed at the present day, for the cure of aneurisms of the femoral and popliteal arteries. The earliest case, of which the particulars are recorded, amounting to a satisfactory proof that the lower extremity might be duly supplied with blood, notwithstanding the femoral artery had been tied high up in the thigh, is the example, related by M. A. Severinus, of a false aneurism of the thigh, about eight finger-breadths below the groin, caused by a musket-ball wound. In this instance, Severinus tied the femoral artery above and below the aperture in it, and not only was the patient's life saved, but the use of the limb also preserved. (*Chirurgiæ Efficacis*, p. 2, *Enarratoria*.) The next authentic case of the ligature of the femoral artery, is that reported by Saviard, where Bottentuit, in 1688, tied this artery on account of a false aneurism, the result of a sword wound, at the inner and upper part of the thigh. The surgeons, called into consultation, were immediately convinced that the only thing to be done was to take up the femoral artery; but they were fearful lest the patient should perish of bleeding ere the opening in the vessel could be found; and, in case the artery were secured, they apprehended that the obstruction of the circulation would be followed by mortification of the limb. The patient was therefore first prepared for his fate by the administration of the sacrament. A band was then applied round the upper part of the

limb, and tightened by means of a stick, with which it was twisted, a piece of pasteboard being put under the knot, in order to render the constriction less painful. The tumor was then opened, the clotted blood extracted, and the opening in the artery detected by slackening the tourniquet. A curved needle, armed with a double ligature, was then introduced under the femoral artery, and one of the cords was tied above, and the other below, the wound in the vessel. Then follows a curious passage, showing the operator's judgment at that time, respecting the impropriety of interposing any cylinder of linen between the knot of the ligature and the artery, as some of the old surgeons at that time used to do, as well as a few of the moderns. "*On ne mit point de petites compresses sur le corps de l'artère au-dessus du nœud, comme font quelques-uns, parce que l'on jugea qu'il étoit d'une grande conséquence de lier très-étroitement une artère si considérable, ce que l'on n'auroit pas été sûr de faire en interposant la petite compresse,*" &c. For greater security, assistants, who relieved each other in turn, kept up constant pressure on the tied part of the vessel for twenty-four hours. In six weeks the patient recovered, and afterwards enjoyed such good health that he went through several campaigns. (*Saviard, Nouveau Recueil d'Observations Chir. Obs. 63. 12mo. Paris, 1702.*)

Now, with respect to these two cases, it merits attention, that, though Heister, Morgagni, and others, endeavoured to explain the success, by supposing that each of the patients in question must have had a double superficial femoral artery in the limb operated upon, both Severinus and Saviard were wise enough to avoid making any such erroneous inference themselves. At a later period, Guattani laid bare the femoral artery, as it passed under Poupert's ligament; compressed it against the ramus of the pubes, by means of graduated compresses, retained with a firm roller; and thus obtained the speedy obliteration of the vessel, and cured an aneurism which had been first injudiciously opened. (*De Externis Aneurysmatibus Hist. 15, 4to. Romæ, 1772.*) In the same book is given the case of an inguinal aneurism, which, when it had continued three months, and become equal in size to a large fist, was attacked with gangrene, whereby the aneurismal sac was quickly destroyed, and the femoral artery obliterated for a considerable extent from the crural arch downwards. The sloughs were thrown off, however, and the ulcer had in a great measure healed when the patient fell a victim to debility. (*Hist. 17.*) Here it is to be remarked, that, during the five weeks this man lived after the obliteration of the femoral artery, above the origin of the profunda, not only the circulation and life of the whole limb were preserved, but the auxiliary arteries, coming from within the pelvis, proved capable of limiting the progress of the mortification of the parts round the aneurism, and of commencing the healing process in a manner which raised great hopes of a cure. A similar fact is also recorded by Dr. Clarke. (*Duncan's Med. Comment. vol. iii.*)

These, and other cases which might be quoted, furnished ample proof of the efficiency of the anastomosing vessels to support the limb, though the femoral artery had been tied, or obliterated in a very high situation.

Besides these facts, surgeons derived every en-

couragement to attempt the cure of popliteal aneurism, by the ligature of the artery above the tumor, from the elucidations given by Winslow and Haller, concerning the numberless inosculation which exist between the upper and lower articular arteries. Haller even drew the conclusion, that, if the course of the blood were intercepted in the popliteal artery, between the origins of the two orders of articular branches, such anastomoses would suffice for carrying on the circulation in the leg. And at length Heister, weighing the anatomical observations of Winslow and Haller and the facts recorded by Severinus and Saviard, first proposed applying to popliteal aneurisms an operation, which, with the exception of those two cases, had until his time been restricted chiefly to aneurisms of the brachial artery. (*Dis. de Genium Structurâ eorumque Morbis. Dis. Chir. Halleri. t. iv.*)

It was in Italy that the earliest operations were undertaken for the cure of popliteal aneurisms, by Guattani, or rather by a German surgeon, named Keysler, as would appear from a letter written by Testa to Cotunni. (See *Pelletan, Clinique Chir. t. i.*) The practice of tying arteries for the cure of aneurism was also adopted in Italy by Molinelli and Mazotti, at a period, when, in other countries, amputation was the measure to which the patient was always subjected. The success obtained by these surgeons, soon led others to imitate them, and by degrees the practice of tying the femoral artery became common both in cases of aneurism and wounds; and from the observations of Heister (*Haller, Disp. Chir. t. v.*), Acrell (*Murray, de Aneurysm. Femoris*), Leslie (*Edin. Med. Comment.*), Hamilton (*B. Bell's Surgery, vol. i.*), Burschall (*Med. Obs. and Inq. vol. iii.*), Leber (*Dehaen, Ratio Medendi, t. vii.*), and Jussy (*Ancien Journ. de Méd. t. xliii.*), it was proved, beyond the shadow of a doubt, that the circulation might continue in the limb after the obliteration of the femoral artery, whether such obliteration were effected by direct pressure or the ligature.

The exact period when the first operation of laying open the tumor and tying the popliteal artery was performed in England, is not, as far as I know, particularly specified. However, judging from the observations made on this practice in the writings of Pott (*Remarks on Palsy, &c. 8vo. Lond. 1779*), of Wilmer (*Cases and Remarks in Surgery, 8vo. Lond. 1779*), of Kirkland (*Thoughts on Amputation, 8vo. Lond. 1780*), and of others, it is clear that this method of treatment had been often done in this country earlier than the dates of those works, and, as would appear, with little or no success. The earliest attempt of this kind in France was made by Chopart in 1781 (*Roux Nouveaux Elémens de Méd. Opératoire, t. i. p. 556*), about five and twenty years after the examples set by Guattani in Italy; but Chopart failed in his endeavours to repress the bleeding from the exposed cavity of the tumor, and was therefore obliged to amputate the limb. Subsequently to this attempt, the operation was undertaken by Pelletan in two instances, the terminations of which were successful: consequently, this surgeon may be regarded as entitled to the honour of having proved to his countrymen the possibility of curing the popliteal aneurism by laying open the tumor, and securing the artery in the ham.

The severity and frequent ill success of this

method of operating I have already noticed, nor shall I repeat the objections to it. With respect to the Hunterian practice, the great peculiarities of which were tying the artery at some distance above the disease, and not opening the swelling at all, Richerand seems offended that Hunter's name should be affixed to an operation, which he conceives was in reality the invention of Guillemeau. Here we observe *Ætius* again puts in a prior claim, and with much more effect, because the method of which he speaks, truly resembled Mr. Hunter's, inasmuch as the vessel is directed to be tied at some distance above the swelling, while Guillemeau only tied the artery close above the disease, and *opened the swelling, a serious deviation from the Hunterian practice.*

Guillemeau, a disciple of Ambrose Paré, having to treat an aneurism at the bend of the arm, the consequence of bleeding, exposed the artery above the tumor, tied this vessel, then opened the sac, took out the coagulated blood, and dressed the wound, which healed by suppuration. After more than a century, Anel, on being consulted about a similar case, tied the artery above the swelling, which was left to itself. The pulsation ceased, the tumor became smaller, and hard, and after some months no traces of the disease were perceptible.

In 1785, Desault operated in the same manner for a popliteal aneurism: the swelling diminished by one half, and the throbbings ceased; on the twentieth day it burst; coagulated blood and pus were discharged in large quantities; and the wound, after continuing a long time fistulous, at length healed. Towards the end of the same year, Hunter applied the ligature somewhat differently; instead of placing it close to the swelling, or directly above it, he put it on the inferior part of the femoral artery. (See *Richerand, Nosogr. Chir.* t. iv. p. 98, 99, edit. 2.) Unquestionably Anel did, in one solitary instance, tie the brachial artery immediately above an aneurism at the bend of the arm, and effected a cure without opening the swelling (*Suite de la Nouvelle Méthode de guérir les Fistules lachrymales*, p. 251, Turin, 1714); but he did not think of applying the plan to the femoral artery, or draw the attention of French surgeons sufficiently to the matter, to make them imitate his operation; on the contrary, the method fell into oblivion, and was never repeated. With regard to Desault's operation, said to have been done in an earlier part of 1785 than Mr. Hunter's first operation, it is only necessary to say, that Desault tied the popliteal artery itself, while the grand object in Mr. Hunter's method was to take up the femoral artery, at a distance from the disease, and that it is this last mode alone which has gained such approbation, and been attended with unparalleled success.

The French surgeons have not practised the Hunterian operation with the same degree of success with which it has been performed in England, and, consequently, they have often returned to the old method of opening the sac, &c. Even Boyer averred, a few years ago, his relinquishment of what he calls Anel's plan. (*Traité des Mal. Chir.* t. ii. p. 148.) But we shall not be surprised at this ill success, when we hear that some of them neglected, for a long while, the right principles on which ligatures ought to be applied to arteries, as explained by Dr. Jones in his work on hemorrhage.

Even Baron Dupuytren, until a late date, adhered to the use of ligatures of reserve; while Boyer applied not less than four loose ligatures round the artery, besides two tight ones; and consequently a large portion of the vessel lay separated from its natural connexions, and irritated by these extraneous substances. Hunter's first operation nearly failed also on account of so many ligatures, none of which were tightened so as to cut through the inner coats of the artery, and thus promote its closure. (See *HEMORRHAGE*.) At length, however, Dupuytren, and several other distinguished surgeons in France, convinced of the inutility and danger of ligatures of reserve, totally discontinued their employment. (See *Leçons Orales de Clin. Chir.* t. iv. p. 531.) The following passage also shows the valuable reforms which have taken place in France in the mode of tying arteries and the treatment of aneurism. "The process generally employed at the present day," says Baron Dupuytren, "is that of Anel or Hunter. When an artery is tied in this plan, it is exposed, if possible, at a point far enough from the aneurism for the vessel to be perfectly healthy, and in a situation where it is superficial; so that the neighbouring veins and nerves may be more easily separated from it, and the ligature more conveniently tightened, in a proper degree. Another, not less important precept, is to preserve above the wound, a sufficiency of collateral branches to keep up the circulation in the lower part of the limb after the operation, and to make the incision so that the ligatures may not be applied too near any large collateral vessels, particularly the superior ones, because their immediate proximity to the ligatures is one of the causes most to be apprehended of secondary hemorrhage. The incision should be extensive enough to let what is requisite be easily done to the artery, and *the fascia should be even more freely divided than the integuments.*" (*Op. et vol. cit.* p. 516.) With reference to the operation for popliteal aneurism, *Rosenmüller's Chir. Anat. Plates*, part iii. tab. 8 and 9; Scarpa's and Tiedemann's matchless engravings; *Haller's Icones*; *Manec, de la Ligature des Artères*, pl. 9 and 10; and *Elias Bujalsky, Tabulæ Anat. Chir.* Petropol. 1828; deserve to be consulted.

ANEURISMS OF THE LEG, FOOT, FOREARM, AND HAND.]

It is not long since doubts were entertained of the possibility of curing an aneurism at the upper part of the calf of the leg by tying the femoral artery in the middle of the thigh. (*Instituto Ital. di Scienze ed Arti*, vol. i. parte ii. p. 266.) The author here referred to was led by this uncertainty to have recourse in one instance to the severe method of laying open the tumor, in order to get at the vessel lower down. On this case, Scarpa makes some correct reflections: The operator (says he) assured himself, that, *on compressing the femoral artery at the upper part of the thigh, the tumor at the top of the calf ceased to pulsate; and that, when the compression was continued for some time, the swelling partly disappeared, and became softer.* It ought to have been evident, therefore, that the aneurism might have been cured by tying the trunk of the femoral artery, as described in the foregoing section. In Scarpa's work is a case in which an aneurism at the bifurcation of the popliteal artery was cured by the ligature of the

femoral artery. (See p. 541, ed. 2.) Mr. Hodgson has seen three aneurisms, situated at the commencement of the tibial arteries, cured by the same operation. (*On Diseases of Arteries, &c.* p. 437.) But, as Scarpa remarks, though the Hunterian operation answers in the cure of aneurism in the bend of the arm, and at the upper part of the calf of the leg, it is not so effectual for aneurisms situated on the back or palm of the hand, or the dorsum, or sole of the foot. The free communication, which the ulnar and radial arteries keep up with each other in the hand, and the tibial arteries have with each other in the foot, prevent the operation from succeeding, whether the brachial or femoral artery, or one of the two large arteries of the forearm, or leg, be tied. In proof of this statement, Scarpa cites two cases of aneurism seen by himself; one on the instep, the kind of case seen also by Guattani; the other in the sole of the foot; and a third case of the same disease in the latter situation; all of which were found to be incurable by the ligature of the anterior tibial artery. (P. 311.) Scarpa thinks, however, that the operation of tying this vessel where it passes over the dorsum of the foot might succeed, if aided by compression, applied so as to stop the current through the other main channel; and he seems to approve of this practice, because the plan of tying the artery above and below the disease (which is the most certain means of cure) could not be done without extensive incisions in the sole of the foot. In an aneurism at the lower part of the leg, Mr. Hodgson judiciously insists upon the prudence of tying the artery as near as possible to the tumor, because the recurrent circulation, through the large inosculation in the foot, might still cause the swelling to enlarge, in consequence of the blood sent into the sac from the lower extremity of the vessel passing through the aneurismal cavity into branches arising from the artery between the aneurism and the ligature. (P. 438.) However, in one case of aneurism of the anterior tibial artery, Mr. H. Cline applied a ligature just above the tumor without success, and Sir Astley Cooper expressly recommends making an incision in the sac, and applying a ligature both above and below the swelling. (*Lectures, &c.* vol. ii. p. 63.) When an aneurism arises from the radial, ulnar, or interosseous arteries near the elbow, tying the brachial will suffice; but if the disease be lower down, the vessel from which it proceeds must be taken up near the swelling. (*Hodgson*, p. 393.) A case, strikingly illustrative of this truth, is recorded by Mr. Liston:—J. M. P., aged nineteen, applied to him on the 28th of July, on account of an aneurism of the left radial artery, about the middle of the forearm, occasioned by a wound. The tumor was as large as a walnut, and so compressible that it could easily be made to disappear. Pressure was tried at first, with apparent benefit; but, as it did not succeed, the humeral artery was tied on the 8th of August, and with the effect of completely removing the tumor. On the eighteenth day afterwards, however, a small slough was detached from the cicatrix, and about three o'clock next morning a violent hemorrhage took place. Mr. Liston then deemed it necessary to lay open the sac, and tie the artery above and below the wound in it. (See *Edin. Med. Journ.* No. 90, p. 4.)

Scarpa mentions a case, where the dorsal artery

of the thumb was wounded; but as the hemorrhage returned several times, and pressure failed in suppressing it, the surgeon took up the radial artery at the wrist. After cutting off this direct current of blood towards the injured vessel, pressure on the wound proved effectual. Three months afterwards, the patient having died, the radial artery was found impervious for three finger-breadths below where the ligature had been applied, and the dorsal artery was likewise obliterated from the root of the thumb to the beginning of the palmar arch.

Mr. Todd has published a case, in which he cured a large aneurismal swelling of the posterior side of the forearm by tying the brachial artery. From the description, I conclude that the disease was an aneurism by anastomosis, as it is termed; but the particulars given by the author leave some doubt on this point. (See *Dublin Hospital Reports*, vol. iii. p. 135.)

The manner of exposing and tying the principal arteries of the leg and forearm will be described under the term ARTERIES.

OF ANEURISMS HIGH UP THE FEMORAL ARTERY.

Several facts, already specified in the preceding columns as having occurred many years before the operation of tying the external iliac artery was attempted, amounted to a full proof, that the circulation might go on in the lower extremity, notwithstanding the artery in the groin were tied, or obliterated. On this point, some of Guattani's cases were most decisive.

The ligature of the external iliac artery, for aneurisms of the femoral artery in the bend of the groin, has now been practised so frequently, and the instances of success are so numerous, that all doubt concerning the propriety and utility of the attempt has entirely ceased. The French, who evinced great backwardness in espousing the Hunterian method of operating for aneurisms, though it is decidedly one of the greatest improvements in modern surgery, at one period showed great reluctance to practise the operation of tying the external iliac artery. M. Roux, however, who was in London about twenty years ago, saw the thing done, and his testimony, no doubt, had considerable influence in quickening the adoption of this bold, but, on the whole, very successful measure, by his brethren in the capital of France. Still, as M. Roux remarks, "We cannot but blame the indifference with which the operation is mentioned in some of the latest French surgical publications. At this moment (1815) we can reckon twenty-three facts relative to tying the external iliac artery, and on fifteen of the patients it has perfectly succeeded. In these twenty-three operations, I comprehend the two which were done in France; one at Brest, by Delaporte, and the other at Lyons, by Bouchet; cases, the authenticity of which cannot be doubted. In the number of successful cases, is to be comprised Bouchet's operation, since the patient lived more than a year afterwards, and then died of the consequences of an inguinal aneurism of the opposite side.

"Sir A. Cooper alone had tied the external iliac artery six times before my journey to London, and during my stay there I saw him perform the operation once. Four of his patients were entirely well; one of the three others died, the thirteenth week after the operation, of the bursting of an

aneurism of the aorta. At this period, the circulation in the limb had been re-established. I saw the limb after it had been injected, amongst Sir A. Cooper's anatomical preparations. Large and beautiful anastomoses existed round the pelvis, between the dilated branches of the internal iliac and femoral arteries. With respect to the sixth patient, the leg mortified, and the thigh was amputated without success. The seventh died of hemorrhage, which took place on the fourteenth or fifteenth day after the operation." (*Parallèle de la Chir. Angloise avec la Chir. Française*, p. 275, 276.) Sir Astley Cooper had tied the external iliac artery in nine cases (see *Lancet*, vol. ii. p. 44); and the operation is now so common, that scarcely a week passes without some record of its performance in one part of the world or another.

The many facts exemplifying the propriety of this operation must have been highly gratifying to Mr. Abernethy, by whose judgment it was first suggested, and by whose enterprising hand it was first performed.

Mr. Abernethy was called upon on several occasions to take up the external iliac artery, and every one of these cases proved that the anastomosing vessels were fully capable of conveying blood enough into the limb below, and that a vessel even of this size could become permanently closed after being tied. Three of the operations in which Mr. Abernethy took up the external iliac artery, the very first examples of this practice, I was an eye-witness of, the cases having occurred at St. Bartholomew's Hospital, at the time when I was an articulated student there. (See *Abernethy's Surg. and Physiol. Essays, and Surgical Obs.* 1804; *Edin. Med. and Surg. Journal for January*, 1807.)

In Mr. Abernethy's first operation, performed in 1796, an incision about three inches in length, was made through the integuments of the abdomen, in the direction of the artery, and thus the aponeurosis of the external oblique muscle was laid bare. This was next divided from its connection with Poupart's ligament, in the direction of the external wound, for the extent of about two inches. The margins of the internal oblique and transverse muscles being thus exposed, Mr. Abernethy introduced his fingers beneath them to protect the peritoneum, and then divided them. Next he pushed this membrane, with its contents, upwards and inwards, and took hold of the external iliac artery with his finger and thumb. It now only remained to pass a ligature round the artery and tie it; but this required caution, on account of the contiguity of the vein to the artery. These Mr. A. separated with his finger, and introducing a ligature under the artery with a common surgical needle, tied it about an inch and a half above Poupart's ligament.

The following was the method which Mr. Abernethy adopted in the second instance of tying the external iliac artery.

An incision, three inches in length, was made through the integuments of the abdomen, beginning a little above Poupart's ligament, and extending upwards; it was more than half an inch on the outside of the upper part of the abdominal ring, to avoid the epigastric artery. Here I may remark, that as the epigastric artery ascends obliquely inwards between the fascia transversalis and the peritoneum, near the internal border of the inner ring, the usual distance between which

and the abdominal ring is an inch and a half, the place chosen by Mr. Abernethy for the incision did not in reality leave the epigastric artery unexposed to danger. The aponeurosis of the external oblique muscle was next divided in the direction of the external wound. The lower part of the internal oblique muscle was thus uncovered; and the finger being introduced below the inferior margin of it and of the transversalis muscle, they were divided with the crooked bistoury for about one inch and a half. Mr. Abernethy now introduced his finger beneath the bag of the peritoneum, and carried it upwards by the side of the psoas muscle, so as to touch the artery about two inches above Poupart's ligament. He took care to disturb the peritoneum as little as possible, detaching it to no greater extent than was requisite to admit his two fingers to touch the vessel. The pulsations of the artery made it clearly distinguishable, but Mr. Abernethy could not put his finger round it with facility. In order to be able to do so, he was obliged to make a slight incision on each side of it. Mr. A. now drew the artery gently down, so as to see it behind the peritoneum. By means of an eye-probe, two ligatures were conveyed under the vessel; one of these was carried upwards as far as the artery had been detached, and the other downwards; they were firmly tied, and the vessel was divided in the interspace between them. (*Surg. Observ.* 1804.)

Mr. Freer, of Birmingham, who may claim the honour of having seconded Mr. Abernethy in this new practice, made an incision about one inch and a half from the spine of the ilium, beginning about an inch above it, and extending it downwards about three inches and a half, so as to form altogether an incision four inches and a half long, extending to the base of the tumor. The tendon of the external oblique being exposed, was carefully opened, and also the external oblique, when the finger, being introduced between the peritoneum and transversalis, served as a director for the crooked bistoury, which divided the muscle. Avoiding all unnecessary disturbance, Mr. Freer separated the peritoneum with his finger, till he could feel the artery beating, which was so firmly bound down that he could not get his finger under it without dividing its fascia. The vessel having been separated from the surrounding parts, a curved blunt needle, armed with a strong ligature, was put under it, and tied very tight, with the intention of dividing the internal coats of the vessel. The operation led to a perfect cure. (*Freer, On Aneurism*, p. 83, 4to. 1807.) Mr. Tomlinson, of the same town, was also an early performer of the operation: he applied only one ligature, and, of course, left the artery undivided; the event was completely successful.

The following is Sir Astley Cooper's mode of operating: A semilunar incision is made "through the integuments, in the direction of the fibres of the aponeurosis of the external oblique muscle. One extremity of this incision will be situated near the spine of the ilium, the other will terminate a little above the inner margin of the abdominal ring. The aponeurosis of the external oblique muscle will be exposed, and is to be divided throughout the extent and in the direction of the external wound. The flap, which is thus formed, being raised, the spermatic cord will be seen passing under the margin of the internal oblique and transverse muscles.

The opening in the fascia, which lines the transverse muscle, through which the spermatic cord passes, is situated in the midspace between the anterior superior spine of the ilium and the symphysis pubis. The epigastric artery runs precisely along the inner margin of this opening, beneath which the external iliac artery is situated. If the finger, therefore, be passed under the spermatic cord, through this opening in the fascia, it will come into immediate contact with the artery, which lies on the outside of the external iliac vein. The artery and vein are connected together by dense cellular membrane, which must be separated to enable the operator to pass a ligature, by means of an aneurism needle, round the former." (See *Hodgson, On Diseases of Arteries*, p. 421, 422.)

The foregoing incision, the convexity of which is turned outward and downward, I think, should extend from within and a little above the anterior superior spinous process of the ilium to above and a little within the middle part of Poupart's ligament, the exact point under which lies the internal ring, behind which the external iliac artery is to be found. As soon as the tendon of the external oblique muscle has been divided, the internal oblique and transverse muscles may be cautiously cut with the aid of a director; and then the fascia transversalis either divided in the same way, or torn through with the end of the scalpel or director. Care must be taken to avoid the epigastric artery, which runs from the pubic side of the external iliac to the inner side of the incision. Baron Dupuytren, in performing the operation at the Hôtel-Dieu, in 1821, wounded the epigastric artery. (See *Averill's Operative Surgery*, p. 37.) The hemorrhage was so copious, that two ligatures were required. The patient afterwards died of peritonitis, which, in all probability, was brought on by the disturbance of the parts in the proceedings requisite for securing the ends of the wounded vessel. Hence, in operating according to Sir A. Cooper's plan, after pushing upwards the lower border of the internal oblique and transversalis, together with the spermatic cord, if the fascia transversalis is to be cut, and not torn, or if the inner ring, the opening in that fascia, is to be dilated, the requisite incision should be made with a probe-pointed bistoury in the direction towards the anterior superior spinous process of the ilium, and away from the epigastric artery. Mr. Guthrie has seen the epigastric artery divided in this operation, and two ligatures placed upon it without any inconvenience occurring. When such practice is adopted, he rates the importance of the accident much lower than I am inclined to do; for he observes, "I have reason to know that this artery is made a greater bugbear of than there is any occasion for in all operations on these parts. If the surgeon has unluckily divided it, either in this or any other operation, all that he has to do is to enlarge the incision, and tie both the divided ends; and I have no hesitation in saying, it will not be of any consequence, either in this operation, or one for hernia. If a man has been so unfortunate as to have a wound in his peritoneum, of a quarter or half an inch in extent, two ligatures on the epigastric artery, and a slight increase in the extent of the external incisions, add little or nothing to the danger, which only takes place in reality when the wound is closed up, and the artery is allowed to bleed internally." (*Guthrie, On Dis. of Arteries*, p. 376.) While I approve of

the practice of securing the two ends of the epigastric artery in a case of this description, the accomplishment of it would not be so easy as the delivery of the proper advice; and where the peritoneum is cut, as in examples of hernia, blood would be likely to be effused in the cavity of the peritoneum before the ends of the vessel could be secured. In taking them up also a considerable disturbance and irritation of the parts would necessarily be produced. For such reasons, and on account of the generally fatal termination of a wound of the epigastric artery, I cannot but view this accident as a truly perilous one. The external iliac vein must never be included in the ligature, as such a proceeding would cause a dangerous interruption of the return of the blood.

Mr. Norman, of Bath, who has tried both modes of operating, found that proposed by Sir A. Cooper a more easy way of finding the external iliac artery than the longitudinal incision practised by Mr. Abernethy. "The objection (says Mr. Norman) to Sir A. Cooper's mode of operating in cases where the tumor extends high up, is by no means well founded; for the lower part of the bag of the peritoneum, lying on the edge of Poupart's ligament, must in every case be exposed and detached, in order to get at the artery, which lies behind the posterior part of that membrane, and this is most easily effected by an incision in the direction of Poupart's ligament; whilst two thirds of the longitudinal incision are made on a part of the peritoneum, which lines the abdominal muscles, and the lower portion only of the incision reaches that part of the membrane which is to be separated. The consequences of this are, that the peritoneum is in much greater danger of being wounded, and that the probability of a hernia forming after the cure is much increased by the extensive division of the oblique muscles." (See *Med. Chir. Trans.* vol. x. p. 101.) These remarks are well founded, and they coincide with some observations made many years ago by M. Roux, who, while he inclined to Mr. Abernethy's method, saw the disadvantage of letting the direction of the wound in this instance correspond to the course of the artery. Hence, after many trials on the dead subject, he laid down the rule, that the beginning of the wound should never be further than half an inch from, and a very little higher than, the anterior superior spine of the ilium, and that it should be carried very obliquely downwards, to the middle of Poupart's ligament. (See *Nouveaux Elémens de Méd. Op.* t. i. p. 747, &c.)

Mr. Todd also, after repeated trials of Mr. Abernethy's and Sir Astley Cooper's methods on the dead subject, concluded that the plan, recommended by the latter afforded the greatest facility of applying the ligature to the artery, because more room was obtained by it, and with less disturbance of the peritoneum, than in the other way. Where, however, it becomes necessary to apply a ligature to a higher part of the artery, in consequence of secondary hemorrhage, Mr. Todd conceives that Mr. Abernethy's method should be adopted. (See *Dublin Hospital Reports*, vol. iii. p. 92.)

In a case operated upon by Mr. Kirby, a hernia followed, in the situation where the abdominal muscles had been divided. (See *Cases with Obs.* p. 109, 8vo. Lond. 1819.)

In one case, Dr. Post found the peritoneum so

thickened and diseased, that he could not raise it from the subjacent parts, and he was obliged to make an opening in it. The protruding viscera were then pushed back, and, with a needle, a ligature was introduced under the artery, the peritoneum being also included in the ligature. Notwithstanding the disadvantageous method of operating, and the return of pulsation in the swelling, the patient had so far recovered in three months, that he had regained the use of the limb. (See *American Med. and Phil. Reg.* vol. iv. p. 443.) Both the external iliac arteries of the same individual were tied in succession by Mr. Tait; one on the 8th of May, 1825, and the other on the 16th of April, 1826; and this with entire success, notwithstanding the peritoneum was wounded in one of these operations. M. Arendt also took up both the external iliac arteries in one patient, and, though there was only an interval of a week between the operations, the case had a very favourable termination. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 175.)

In one remarkable case, Mr. Newbiggin, by tying the external iliac artery, cured both an inguinal and a popliteal aneurism together. (See *Edin. Med. and Surg. Journal for Jan.* 1816, p. 71, &c.)

The many operations, which have now been done on the external iliac artery, impress me with a conviction that, in subjects under a certain age, there is no reason to fear that the anastomoses will not generally suffice for the supply of the lower extremity. Out of twenty-five cases the particulars of which I formerly collected, there were only three in which the limb was attacked by gangrene. These three were patients of Sir A. Cooper, M. Bouchet of Lyons, and Mr. Collier. The proportion is not so much as one in eight. The three instances of gangrene were not all in the circumstances which permitted the event to be imputed to the anastomoses not having had sufficient time to enlarge, though perhaps Mr. Collier's case was such. On the other hand, we are to notice that Dr. Cole's patient was operated upon a few days after the wound, and yet the limb was duly supplied with blood, and did not become gangrenous. The same important facts were likewise exemplified in the remarkable case, where M. Velpeau was suddenly called upon to tie the external iliac artery, which had been accidentally wounded with a knife. Here, although there had been no preliminary dilatation of the collateral vessels, either by a trial of pressure, or by the presence of an aneurism, a ligature was at once put on the external iliac artery, with a perfectly successful result. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 175.) It appears therefore to me, that the occasional occurrence of gangrene cannot be admitted as a just reason for delay, until the collateral vessels have had time to enlarge. I believe, that in all aneurismal diseases, early operating is the best and most judicious practice. This was one principal cause, as Kirkland observes, which occasioned the bad success of the old surgeons in the treatment of popliteal aneurisms, and he foretold, many years ago, that operations for the cure of aneurisms would answer better, if not deferred so long as formerly. (See *Thoughts on Amputation*, &c. 8vo. Lond. 1780.) I join Kirkland in this sentiment, not without recollecting that all aneurisms are attended with a chance of getting well spontaneously in the course of time.

I saw the inguinal aneurism which did so, under Dr. Albert, in the York Hospital; but as this is a rare incident, I do not believe that it ought to influence us against having speedy recourse to an operation. Besides, the cure by inflammation and sloughing appears to me to be attended in reality with more peril than a well executed operation, and, consequently, has less recommendations than many may imagine. Had not Dr. Albert's patient been a very strong man, he would certainly have fallen a victim to the extensive disease which the bursting and sloughing of the tumor created. Thus, Delaporte's patient died of the mass of disease which the tumor itself made; for it had been suffered to attain too large a size, so that, when it inflamed, the effects were fatal. (See *Richerand, Nosogr. Chir.* t. iv. p. 113, edit. 4.)

I believe Dr. Wilmot's observation is perfectly correct, that if a comparison were made between the operation of tying the external iliac artery and that of tying the artery in the thigh, we should find the recoveries after the first more frequent, in proportion to the number of times it has been done, than after common operations lower down. (See *Dublin Hospital Rep. &c.* vol. ii. p. 214.)

[The results of the ligature of the external iliac artery are very favourable. According to Norris, of one hundred cases in which the vessel has been tied for aneurism, seventy-three have recovered, and twenty-seven died. The most frequent cause of death was gangrene of the limb, and next to that secondary hemorrhage.]

Pulsation recurred in six cases, but one of these proved fatal; and suppuration of the sac happened in thirteen instances, of which three had a fatal result.]

The greatest artery that conveys blood into the lower extremity, after the external iliac has been tied, is the gluteal: but besides it, the ischiatic, the obturator, and the external pudic, which anastomoses freely with the internal pudic, are important vessels in keeping up the circulation.

In one case, operated upon by Mr. J. C. Warren, the epigastric artery arose from the anterior and inner part of the sac, and gave origin to the obturator, while the circumflexa ilii originated from the outer part of the sac. All these vessels were greatly enlarged, and the epigastric rendered the necessary detachment of the external iliac very difficult. (See *New England Journ.*)

Some particulars of inguinal aneurisms, in which Sir A. Cooper, Mr. James, and Mr. Murray tied the aorta, will be hereafter noticed. (See AORTA.)

Rosenmüller's Chir. Anat.; *Tiedemann's Tabulæ Arteriarum*, Carlsruhæ, 1822; the plates in Scarpa's great work, *Sull Aneurisma Reflessioni*, &c. Par. 1804; *J. P. Manec, De la Ligature des Artères*, pl. ix.; and *Elias Bujalsky's Tabulæ Anat. Chir.* Petropol, 1828, tab. x. et xi., in illustration of the operation of tying the external iliac artery, all merit notice. Under the head of ARTERIES, additional instructions will be offered on the mode of taking up the external iliac artery.

CASES OF GLUTEAL ANEURISM CURED BY TYING THE INTERNAL ILIAC ARTERY.

The gluteal artery is large; from its situation, liable to wounds; from its size, subject to aneurism. Dr. Jeffray, of Glasgow, was consulted in a case where the gluteal artery had been wounded, and an aneurism resulted. He urged the propriety of

tying the vessel where it had been injured. This sensible advice was at first rejected; and when the friends at last consented, the operation was too late, as, while preparation was making for it, the tumor burst, and the patient expired in a few moments. Theden also mentions an instance, in which the gluteal artery was wounded in the dilatation of a gunshot wound, and the patient lost his life. (See *Scarpa, On Aneurism*, p. 407, ed. 2.) Mr. John Bell, however, tied the gluteal artery in a case where it was wounded, and the patient was saved.

Mr. Stevens, surgeon in Santa Cruz, the gentleman who has proved the practicableness of putting a ligature round the internal iliac artery, informs us, that one of the first surgeons in London had a patient with gluteal aneurism. The tumor was large; allowed to burst; and the person bled to death. "I sincerely trust," says he, "that the following case may be the means of preventing such an occurrence in future. Maila, a negro woman, from the Bambara country in Africa, was imported as a slave into the West Indies in the year 1790. She was purchased for the estate Enfield Green, now the property of the heirs of P. Ferrall, Esq. I saw her first in the beginning of December, 1812. She had a tumor on the left hip, over the sciatic notch. It was nearly as large as a child's head, and pulsated very strongly. She could assign no cause for the disease. It had commenced about nine months before, with slight pain in the part; and had gradually increased to its present size. She was now much reduced, in great misery, and ready to submit to any operation." (See *Medico-Chir. Trans.* vol. v. p. 425.) Mr. Stevens had tied the internal iliac on the dead body, and believed that it might be done with safety on the living. The following is the account of the operation: "On the 27th of December, 1812 (says Mr. Stevens), I tied the artery, in the presence of Dr. Lang, Dr. Van Brackle, Mr. Nelthropp, and Mr. Ford, the manager of the estate. An incision, about five inches in length, was made on the left side, in the lower and lateral part of the abdomen, parallel with the epigastric artery, and nearly half an inch on the outer side of it. The skin, the superficial fascia, and the three thin abdominal muscles, were successively divided; the peritoneum was separated from its loose connection with the iliacus internus and psoas magnus; it was then turned almost directly inwards, in a direction from the anterior superior spinous process of the ilium, to the division of the common iliac artery. In the cavity, which I had now made, I felt for the internal iliac, insinuated the point of my forefinger behind it, and then pressed the artery betwixt my finger and thumb. Dr. Lang now felt the aneurism behind; the pulsation had entirely ceased, and the tumor was disappearing. I examined the vessel in the pelvis; it was healthy, and free from its neighbouring connections. I then passed a ligature behind the artery, and tied it about half an inch from its origin. The tumor disappeared almost immediately after the operation, and the wound healed kindly. About the end of the third week, the ligature came away, and in six weeks the woman was perfectly well."

This is the first example, in which the internal iliac was tied. The operation was not attended with much difficulty or pain, and not an ounce of blood was lost. Mr. Stevens had no difficulty in

avoiding the ureter, which, when the peritoneum was turned inwards, followed it. Had it remained over the artery, he could easily have turned it aside with his finger. (See *Med. Chir. Trans.* vol. v. p. 422, &c.)

The woman enjoyed good health for ten years, and then died of an affection of the chest. The body was opened, and the internal iliac artery found impervious at the point where the ligature had been applied. The ischiatic artery had the appearance of a ligamentous cord, but the gluteal artery was pervious. The pelvis was then removed, brought from Santa Cruz, and deposited in the Museum of the Royal College of Surgeons in London. In the further examination of the parts, the ileo-lumbar artery was found to have arisen just above the part where the ligature had been applied, and consequently the internal iliac was pervious from its origin to this point. The particulars of the dissection, as given by Mr. Richard Owen, are remarkably interesting. I shall only notice those circumstances which strike me as peculiarly deserving of record. An incision being made into the common iliac, and continued down to the part where the internal iliac became contracted, it was found there to have become completely obliterated. In the state of a ligamentous cord, the internal iliac descended towards the ischiatic notch for the space of an inch, and then suddenly resuming its natural diameter, it again became pervious, and so continued for the extent of half an inch; the gluteal artery arising from the lower part of this space, a sacro-lateral vessel from about the middle, and the obturator artery from the upper part of it. The latter vessel was entirely obliterated; but the sacro-lateral was pervious, of the size of a crow-quill, and passed inwards to the second sacral foramen; whilst the gluteal artery received, close to its origin, two vessels, as large as the preceding, given off from the sacro-lateral artery. The ischiatic was impervious. The gluteal artery was of its natural size. An oblong tumor of the sciatic artery was detected, three inches and a half in length, between the tuberosity of the ischium and the great trochanter, doubtless the remains of the original disease. It was filled with dark-coloured, granular, not lamellated blood. From the ischiatic notch to the tumor, the artery was completely obliterated, its texture altered, and the remains of its cavity filled with indurated and partly calcareous matter. From the lower part of the swelling, the sciatic artery proceeded down the posterior part of the thigh, and was nearly as large as the femoral. Its calibre did not, however, correspond to its apparent magnitude, its coats being vastly thickened. It was obliterated for about the space of an inch below the sac, but became pervious again after receiving an anastomosing vessel from the profunda. Mr. Owen infers from several circumstances, which he specifies, that the aneurism was of the true kind. Amongst the things highly deserving notice in this case was the open space maintained by the collateral circulation in the trunk of the artery, between the ligature and the aneurism. (See *Med. Chir. Trans.* vol. xvi. p. 221. &c.)

A second instance, in which the internal iliac artery was tied, was some time ago communicated to the public. The operation was performed by Mr. Atkinson, of York, on account of a gluteal aneurism. The following are a few of the particulars:—

Thomas Cost, aged twenty-nine, presented himself at the York County Hospital, April 29th, 1817. He was a tall, strong, active bargeman, not corpulent, but very muscular. He was enduring great pain from a large, elastic, pulsating tumor, situated under the glutæus of the right side; an obvious aneurism. It had existed about nine months, and was the consequence of a blow from a stone. In a consultation with Dr. Lanson and Dr. Wake, the necessity of the operation was determined upon, and it was performed on the 12th of May, without any material difficulty or interruption, except such as was the consequence of the division of, and bleeding from, the small muscular arteries. Having got command of the internal iliac artery within the pelvis, which, says, Mr. Atkinson, required the complete length of the fingers to accomplish, it was tied. Sufficient proof of its being the identical artery was repeatedly obtained, by the pressure upon it stopping the pulsation, and causing a subsidence of the tumor. Dr. Wake, Mr. Ward, and all the pupils were quite assured of the circumstance. The artery being then tied, the pulsation of the swelling entirely ceased. Some delay in placing the ligature arose from the needle not being sufficiently pliable; but, for future operations of this kind, Mr. Atkinson very properly recommends the ligature to be put round the artery by means of an instrument, resembling a catheter, the wire of which has a little ring at its extremity, and can be pushed out some way beyond the end of the tube.

The patient went on tolerably well for some time after the operation; the pulse never exceeded 130, and after a time sunk to 85 or 90. He became exhausted, however, partly by the discharge, and partly by hemorrhage, and died on the 31st of May, about nineteen days after the operation. In the dissection, the cavity, on the external part of the peritoneum, in the situation of the incision, was completely filled with coagulated blood. "The ligature, on moving a part of this (blood) with a sponge, readily followed it, and, without doubt, had been disengaged for some days." The internal iliac, which appeared to have been tied, had separated about an inch and a half from the bifurcation with the external iliac. By "separated," I conclude Mr. Atkinson means, that the upper part of the internal iliac was separated from the continuation of the same vessel. (See *Medical and Phys. Journ.* vol. xxxviii. p. 267, &c.) Although this gentleman has not given a very clear account of some part of the dissection, and he has also omitted to describe the place of his external incision, or the exact parts which he divided in the operation, yet I think that all the circumstances of the case, taken together, leave not the smallest doubt of the internal iliac artery having been actually tied. The complete stoppage of the pulsation as soon as the ligature was applied, and the testimony of several respectable practitioners who were present, remove, indeed, all ambiguity. The profession is much indebted to Mr. Atkinson for this important communication, which was in some measure required, in order to confirm Mr. Stevens's similar case, as it is well known that some distinguished anatomists and surgeons in this metropolis formerly expressed strong doubts of the practicable nature of the operation.

The internal iliac artery has since been tied with success by an army surgeon in Russia, upon whom

the late Emperor Alexander settled a pension, as a reward for the skill displayed in the treatment of the case. (See *Averill's Operative Surgery*, p. 39.)

The operation of tying the internal iliac was also performed by Mr. Thomas, of Barbadoes, who sent the preparation of the parts to Sir Astley Cooper, and it is in the Museum of Guy's Hospital. (*Med. Chir. Trans.* vol. xvi. p. 230.) A fifth instance of the application of a ligature to the internal iliac artery took place in the practice of Mr. Hudson, of New York. (See *American Journ. of Med. Sciences* of Feb. 1828, art. v. p. 304.) A semilunar incision, seven inches in length, was made with its convexity towards the ilium, from the vicinity of the umbilicus to that of the abdominal ring. After dividing the parietes of the abdomen, and tying some arteries which bled, the peritoneum was pushed upwards and inwards, and the handle of a scalpel passed under the trunk of the internal iliac artery, which was tied an inch below its origin. The patient recovered.

[Since Stevens's case, the internal iliac has been ligatured six times; of these seven cases, four recovered, and three died; a very considerable amount of success when we take into consideration the depth at which the vessel is situated, the size of the trunk, and its proximity to the centre of the circulation.]

It is very justly observed by M. Velpeau, that the ligature of the internal iliac artery, with regard to its influence on the circulation, is in reality less serious than that of the external iliac, or even the femoral. In fact, it leaves undisturbed all the vessels appertaining to the corresponding limb, while the great pelvic arteries anastomose with one another so freely, that, when one is obliterated, an abundance of blood is promptly conveyed by the others to the organs which the obliterated one is designed to nourish. But the ligature of the internal iliac artery is dangerous in another point of view: first, on account of the difficulties in its performance; and secondly, on account of the unavoidable detachment of parts from one another which are connected together by a large quantity of loose cellular tissue, a texture in which inflammation and suppuration are disposed to spread to a great extent. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 185.)

In a modern publication are given a few particulars of a case, which was supposed to be an aneurism of the gluteal artery, and cured by means of pressure, a light vegetable diet, gentle laxatives, and digitalis. (See *Trans. of the Fellows, &c. of the King's and Queen's College of Physicians in Ireland*, vol. i. p. 41. 8vo. Dub. 1817.) From the very imperfect account here given of the tumor, it is impossible to form any conclusion respecting its nature. Mr. Mayo also briefly mentions a case which was believed to be a false aneurism of the gluteal artery, and which got well without an operation. (*Outlines of Pathology.*)

Sandifort has recorded an instance of an aneurism of the internal iliac artery itself. (See *Tabulæ Anatomicae, &c. Præcedit Obs. de Aneurysmate Arteriæ Iliacæ internæ rariore ischiadis Nervosæ causa.* Fol. Lugd. 1804.)

ANEURISM REQUIRING LIGATURE OF THE COMMON ILIAC ARTERY.

Professor Gibson had occasion to put a ligature round the common iliac artery, in an example of

gunshot wound. "The patient lived fifteen days after the operation, and then died from peritoneal inflammation, and from ulceration of the artery. The circulation in the limb of the injured side was re-established about the seventh day after the artery had been tied." (See *American Med. Recorder*, vol. iii. p. 185; and *Gibson's Institutes of Surgery*, vol. ii. p. 145. Philadelphia, 1825.)

In March, 1827, Dr. Mott took up the common iliac artery in a case of aneurismal tumor protruding considerably in the iliac region, and causing excruciating pain. Dr. Mott's incision, about eight inches in length, extended from the external abdominal ring, to one or two inches above the anterior superior spine of the ilium. The tendon of the external oblique muscle was divided, and also a part of the insertion of the internal oblique and transverse muscles. The operator then cautiously raised the peritoneum with his fingers, and detached it from the tumor and vessels, without doing it the slightest injury. The aneurismal dilatation was found to terminate about half way between the bifurcation of the aorta and the origin of the internal iliac trunk. The ligature was passed from the outside of the vessel, with the aid of an instrument invented by Drs. Parish and Hewson. The protrusion of the intestines rendered this part of the operation most difficult. The exact situation of the ligature was just below the bifurcation of the aorta, and at the side of the sacro-vertebral promontory. As soon as the ligature was tightened, the pulsation of the tumor ceased, its size was lessened, and the agonising pain previously felt subsided. The limb having become cold, was wrapped in cotton and well covered, and, in little more than half an hour, its circulation and temperature were entirely restored. The operation was completely successful. In 1828, the operation of tying the common iliac artery was performed by Mr. Crampton, of Dublin; but the patient died of hemorrhage on the fourth day. In this case, the circulation, heat, and sensibility, which had been seriously interrupted in the limb for a time, were perfectly re-established, and every thing seemed to promise a favourable result, when, on a sudden, the ligature became displaced, and the patient died of internal hemorrhage. In the year, 1833, the common iliac artery was taken up by Mr. Guthrie, for a tumor, supposed by him and some other surgeons to be aneurismal, but which proved to be of a medullary malignant character. The temperature of the limb after the operation diminished, but not much. It was constantly rubbed, day and night, and a hot brick and bottles of hot water applied to the feet. The tumor subsided directly.

After the ligature of the common iliac, the lower extremity is supplied with blood through the anastomoses of the internal mammary with the epigastric, of the uppermost lumbar arteries with the circumflexa ilii, or even the ilio-lumbalis; and, lastly, of the branches of the internal iliac of the sound side with those of the diseased one.

[The results of the ligature of the common iliac are sufficiently encouraging. Of seventeen cases in which this artery was tied, nine recovered. In eleven of the cases the ligature was for aneurism, and of these seven recovered. The remaining four rather died from the magnitude of the disease, or from wound of the peritoneum, than from the operation itself; and in no instance did gangrene occur.]

ANEURISMS OF THE BRACHIAL ARTERY.

Surgical writings contain many histories of aneurisms in the bend of the arm, produced by the puncture of the brachial artery in venesection, or caused by a deep wound inflicted at the bend of the arm, along the inner side of the humerus, or in the axilla. Such cases must indisputably be followed by effusion; but the blood extravasated may spread widely in the cellular tissue, so as to constitute a diffused false aneurism; or it may be confined in one mass, and be bounded by the adhesive inflammation, so as to form a circumscribed false aneurism. Morand and others found, that, along with aneurisms, caused by a wound of the brachial artery, the diameter of the vessel was sometimes enlarged through its whole length, above the seat of the tumor.

The proximate cause of these cases may invariably be traced to the solution of continuity in the proper coats of the artery, and the consequent effusion of blood into the cellular substance. The effect is the same, whether from an internal morbid affection, capable of ulcerating the internal and fibrous coats of the artery, the blood be effused into the neighbouring cellular sheath surrounding the artery, which it raises after the manner of an aneurismal sac; or, the wound of the integuments having closed, the blood issue from the artery, and be diffused in the surrounding parts. The cellular substance on the outside of the wounded vessel, is first injected, as in ecchymosis; the blood then distends it, and elevates it in the form of a tumor, and the intercellular spaces being destroyed, converts it at last into a firm capsule, or aneurismal sac. (*Scarpa*, p. 167.)

The circumscribed or the diffused nature of the aneurism, and the rapidity or slowness of its formation, depend on the greater or less resistance to the impetus of the blood, during the time of its effusion, by the interstices of the cellular substance surrounding the artery, and by the ligamentous fasciæ and aponeuroses, lying over the sac.

While aneurisms, from an internal cause, are not unfrequent in the aorta, thigh, and ham, they are exceedingly rare in the brachial artery; though a few such instances are recorded. (*Scarpa*, 174; *Pelletan, Clinique Chir.* t. ii. p. 4.) Dupuytren, in noticing the great rarity of true aneurisms of the brachial artery, expresses his belief that Pelletan's is the only well authenticated instance of it. The cases quoted by Scarpa from Paletta and Flajani do not appear to him precise enough, and he takes the same view of those reported by Saviard and Hodgson. (See *Clinique Chir.* t. i. p. 265.)

The mode of distinguishing a wound of the brachial artery, in attempting to bleed, and the method of trying to effect a cure by pressure (direct pressure is here meant) are described in the article HEMORRHAGE. From the cases published by Mr. Cusack, it appears that the brachial form of aneurism to which pressure (direct pressure is here meant) is most applicable, and in which it is most likely to effect a cure, is that of circumscribed false aneurism, unattended by inflammation either of the sac or of the surrounding parts. The pressure should be applied to the tumor alone, and not to the artery above; and it should be but slight, until the diminished pulsation and solidity of the swelling indicate that coagula fill the sac; for otherwise the aneurism will become diffused, as happened in one of Mr. Cusack's cases.

(See *Dublin Journ. of Med. Science*, vol. i. p. 124.)

[Compression of the brachial artery above the aneurismal sac is not usually attended by very successful results. This may be partly owing to the aneurism being usually of the traumatic kind, to which compression is not very applicable, but is in a great measure due to the pain inflicted by the pressure on the neighbouring nerves rendering this method of treatment unbearable to the patient.]

Anel was the first who tied the brachial artery, for the cure of aneurism at the bend of the arm, in the same way that Hunter did the femoral, for the cure of aneurisms in the ham; viz. with one ligature above the tumor, without making any incision upon, or into, the sac itself.

The operation is performed as follows:—The surgeon having traced the course of the brachial artery, and felt its pulsations above the aneurism, may either cut down to the vessel immediately above the tumor, or much higher in the long space between the origins of the superior and inferior collateral arteries. The integuments are to be divided in the course of the artery, and also the fascia for the space of about two inches and a half. The surgeon, now introducing his left forefinger to the bottom of the wound, will feel for the hard cord formed by the median nerve, and closely under, or at the side of which, is the artery within its sheath, which is to be opened. The surgeon should cut chiefly on the side next to the internal margin of the biceps, to avoid dividing any of the numerous muscular branches which go off from the opposite side of the artery. He is then to separate the artery from the median nerve and the brachial veins, and with an eye-probe is to pass a ligature under the artery, and then tie it with a simple knot.

In the operation, it should always be recollected, that the median nerve lies in the lower third of the arm, on the inner side of the artery; and, therefore, that the instrument used for putting the ligature under the vessel, should be passed from within outwards, by which means the inclusion of the nerve will be avoided. (See *Boyer, Traité des Maladies Chir. &c.* t. ii. p. 193.)

In the upper third of the arm, the median nerve will be found on the outer side of the artery; in the middle third it crosses superficially over the artery as it gradually changes its position from the outside to the inside of that vessel; occasionally, however, the nerve crosses underneath the artery.

Sometimes the surgeon has a difficulty in discriminating the artery from the median nerve. When there is no pulsation perceptible in the artery, the firmer feel of the nerve is one of the best criterions. Indeed, after dividing the integuments, the hard cord felt under the fascia may be regarded, without any risk of mistake, as the median nerve. However, the best operators are sometimes perplexed. Thus, Dupuytren was operating on a patient who fainted, and, for more than a quarter of an hour, he remained doubtful which was the nerve, and which the artery, and he did not venture to tighten the ligature till the circulation had revived. (*Dupuytren, Clin. Chir.* t. i. p. 282.) And, in another instance, after making an incision, two inches and a half long, in the course of the artery, above the bend of the elbow, he found the subcutaneous cellular tissue gorged with blood, and the cellular sheath, inclosing the median nerve

and brachial artery, thickened and easily torn. A large vein lying across the artery was cut through. The fasciculus, composed of the artery and nerve, were next exposed, and an eye-probe passed under the guidance of a director beneath the artery, as Dupuytren supposed; but, on raising up the probe to ascertain what lay over it, severe pain was felt, followed by numbness in the track of the nerve. Dupuytren, then, by very careful dissection, detached the nerve from the artery, to which he next applied a ligature. (*Op. et vol. cit.* p. 288.)

The importance of avoiding the inclusion of the median nerve in the ligature is great, not only with reference to paralysis, but to gangrene, which Dupuytren never knew follow the ligature of the brachial artery, except when that nerve had been tied together with it. (See *Clin. Chir.* t. i. p. 286.)

Whoever, says Scarpa, shall have the treatment of a *circumscribed* aneurism in the bend of the arm, will no longer, it is to be hoped, follow the method of those, who supposing the tumor to be formed by the dilatation of the artery, used first to divide the integuments over the tumor, insulated the sac, and sought the vessel above and below the aneurism, in order to tie it in two places; and then endeavour to make the sac slough away. The operation is now reduced to the greatest simplicity, viz. tying the artery merely above the tumor. (See *Scarpa*, p. 358, 359.)

The ligature should be placed as near the aneurism as possible, the principal reason for doing it at a distance from the swelling in some other cases not being here applicable. (See *Harrison on the Arteries*, vol. i. p. 167; *Guthrie, On Dis. of Arteries*, p. 333, &c.) The correctness of Scarpa's recommendation of tying the artery only in one place above a circumscribed brachial aneurism is confirmed by the experience of Dr. Colles, who observes, "I have operated repeatedly, and with success, for the cure of brachial aneurism, in consequence of injury to the arteries in performing venesection. I have also frequently assisted others in operating for the same case, and with the same result; and I never yet found it necessary to open the aneurismal sac, or to apply more than one ligature round the artery, and which, I think, ought always to be tied as near as possible to the seat of the disease." (See *Harrison's Surgical Anatomy of the Arteries*, vol. i. p. 170, ed. 2.)

When the aneurism is *diffused*, and accompanied with violent inflammation and swelling of the whole arm, from the excessive distension of the clots of effused blood, Scarpa recommends the old operation of opening the tumor, and tying the artery at the bottom of the sac, above and below the wound made by the lancet. In this method, a tourniquet must be applied to the upper part of the arm, near the axilla; or if the limb be very painful and swelled, it is better to let an assistant compress the artery above the clavicle, against the first rib. The incision having been made into the tumor, and the blood discharged, a probe is to be introduced into the puncture in the vessel, from below upwards, so as to raise the artery. This, being separated from the parts beneath, and the median nerve, for a small extent, is to have two ligatures put under it; one of which is to be tied above, the other below, the wound in the vessel. Then the tourniquet, or pressure, is to be taken off; and if there be no bleeding, the wound is to be brought together. (See *Scarpa*,

p. 359.) With reference to this operation, Rosenmüller's *Chir. Anat. Plates*, part ii. tab. 11.; Scarpa's plates; Tiedmann's beautiful engravings of the arteries; *Manec, De la Ligature des Artères*, pl. vi.; and *Camper's Demonstr. Anat. Pathol.* lib. i. are worth consulting.

From observations made by Mr. Harrison, a doubt may be entertained, whether, even in these circumstances, the adoption of the foregoing plan is always necessary. Indeed, he distinctly declares, that "in no case of *diffused* or circumscribed aneurism at the bend of the elbow have I seen it necessary to open the sac, or the artery below the tumor." "Brachial aneurism," says he, "which commences at the bend of the elbow, in consequence of a wound, is not always circumscribed. Sometimes the tumor extends up the arm between the biceps and triceps muscles, the fascia of the arm preventing its increase in a lateral direction. In one instance I saw the disease extend from the elbow nearly to the axilla. In this diffused aneurism, the surgeon must tie the brachial artery in the upper part of its course, and apply moderate compression along the aneurismal sac. This plan succeeded in the case to which I have alluded, and in which the operation was performed by Mr. Wilmot, in Jervis Street Infirmary; and a perseverance in moderate compression for some weeks, caused the total disappearance of the disease." (See *Harrison's Surgical Anat. of the Arteries*, vol. i. p. 169, ed. 2.) Still, exceptions to the preceding advice may present themselves. Thus the brachial artery has been wounded in venesection precisely at its bifurcation into the radial and ulnar branches. The brachial artery was tied close to the wounded part; but as the bleeding returned, it was secured a little higher up. Amputation was performed, and the patient lost his life. Here it was ascertained that a ligature could scarcely have been applied below the opening in the vessel, so near was this to the bifurcation; and perhaps the radial and ulnar arteries should have been secured. (See *Guthrie, On Dis. of Arteries*, vol. i. p. 332.) While Baron Dupuytren expresses himself in favour of the preference which should generally be given to a single ligature above the tumor in aneurism at the bend of the arm, he admits the possibility of this method failing, the pulsations being only temporarily suspended by it. In simple aneurism it will answer; in what he terms the arterioso-venous aneurism, or varicous aneurism, it will not stop the throbbings. (See *Clinique Chir.* t. i. p. 274.)

A high division of the brachial artery is well known to be a frequent occurrence. If, in consequence of this, two arteries should be exposed in the operation (see *J. G. Crosse in Prov. Med. and Surg. Trans.* vol. v.), the surgeon should endeavour to ascertain by pressure, which vessel communicates with the wound, or sac, and apply the ligature accordingly; but, if the pulsation, or bleeding, cease only when both vessels are compressed, he will be justified in tying both. (See *Harrison's Surgical Anat. of the Arteries*, vol. i. p. 166, ed. 2.)

[*Spontaneous aneurisms of the arteries of the forearm* are of extremely rare occurrence. When met with they require to be diagnosed from pulsating encephaloid tumors, which are not very unfrequently met with in this situation. Their treatment consists in the application of a ligature to the brachial.]

AXILLARY ANEURISMS.

Aneurisms occasionally take place in the axilla, and make it necessary to tie the subclavian artery. A question, here naturally presenting itself, is, whether the surgeon should attempt the operation in the early period of the disease, or wait till circumstances are urgent—the aneurism large and far advanced; the arm œdematous and insupportably painful, from the stretching of the axillary plexus of vessels; the patient worn out by suffering and loss of rest; and the tumor in danger of bursting? In all cases of aneurism, unquestionably, there is a certain chance of the disease getting well spontaneously; and one axillary aneurism, in a man in St. Bartholomew's Hospital a few years ago, had certainly disappeared of itself, as was proved by the account which the patient while living gave of his case, and by the obliteration of the artery, found on inspection after death. We may also find a few instances of subclavian aneurism being cured by Valsalva's treatment. (See *Pelletan, Clin. Chir.* t. i. p. 77; *Cloquet in Archives*, 1834, t. vi. p. 511.)

I believe, however, we ought not to suffer our conduct to be too much influenced by the hope of events which are so unfrequent; and, from the observations which I have made on this subject, it is my decided opinion that the operation should never be delayed so as to allow the tumor to acquire an immoderate size. The operation is always difficult; but the difficulty is seriously increased when the swelling has extended far towards the breast, and has become so large as to push the clavicle considerably upwards. The several examples in which the subclavian artery has now been successfully tied furnish abundant proof that the anastomoses are fully competent to the supply of the limb with blood. The plan, therefore, of delaying the operation long, with the view of allowing the inosculating arteries to enlarge, must be as questionable here as in some other cases of aneurism, and at all events the maxim may be safely advanced, that, previously to the operation, the tumor should never be suffered to acquire an enormous size.

That the limb would receive an adequate supply of blood was well proved, even without the performance of the operation, by cases in which the axillary and subclavian arteries had been rendered impervious by disease; as, for instance, by the pressure of an aneurism of the aorta. (For an account of such facts, the reader is particularly referred to *Hodgson's Treatise on the Diseases of Arteries*, p. 111; *Journ. de Médecine*, by *Corvisart, Leroux, and Boyer*, t. ii. p. 29; *Corvisart, Essai sur les Maladies du Cœur*, p. 215.)

"In these cases," says Mr. Hodgson, "the only unusual circumstance which was observed during the life of the patients, was the deficiency of the pulse at the wrist. The limbs were well nourished, although a considerable extent of the main artery (the subclavian) was obliterated even before it had given off any branches." (P. 47.)

This vessel was tied by Mr. Hall, in Cheshire, when it had been wounded with a scythe, and its ends exposed; the arm was preserved, though it remained somewhat weakened, which might be owing to the division of some large nerve. (See *J. Bell, On Wounds*, p. 60, ed. 3; and *Scarpa*, p. 372.) Mr. White, of Manchester, relates an-

other instance of this vessel being tied in the case of a wound; but mortification of the limb and death followed. Three of the nerves were found included in the ligature. (*Lond. Med. Journ.* v. 4.) In cases of wounds of the axillary, or any other large arteries of the extremities, the surgeon, before proceeding to apply a ligature, should first ascertain the precise place of the wound in the artery; and, for this purpose, it may sometimes be proper, in certain wounds of the shoulder, to make an incision in the axilla, so as to expose the injured part of the vessel; or, if circumstances do not forbid it, the external wound may be dilated, until the exact part where the artery has been wounded is discovered. In proof of the propriety of acting in this manner, and applying a ligature above and below the wound in the vessel, Scarpa quotes a case in which such practice was successful on a patient under M. Maunoir, of Geneva: the artery had been injured with a sabre near the head of the humerus; but, after the wounded part of the vessel had been traced, and secured in the way above suggested, the patient, a boy fourteen years of age, was saved from the dangers of hemorrhage, and recovered the use of his arm, as fast as this was possible, with the loss of the first phalanges of the three last fingers from gangrene. (See *Scarpa, On Aneurism*, p. 412, ed. 2; and *Journ. de Méd.* t. xl. Mars, 1811.)

There are two modes for operating for axillary aneurisms: one, by cutting below the clavicle, in order to take up the axillary artery itself; the other, by making the wound above the bone, for the purpose of securing the subclavian artery at the point where it emerges from behind the anterior scalenus muscle.

The first of these methods has been attempted by Desault, Pelletan, the late Mr. Thomas Keate, Mr. Chamberlaine, &c. In a case of wound of the axillary artery, Desault made an incision, six inches long, below the external third of the clavicle; two thoracic arteries cut were immediately tied; the two lower thirds of the great pectoral muscle were next divided with a bistoury guided on a director: a large quantity of coagulated blood was now discharged; and the artery was directly taken hold of and tied, together with the brachial plexus of the nerves. The arm mortified, and the patient died. This case, we must agree with Scarpa, was not a fair trial of the operation, inasmuch as the inclusion of the plexus of nerves in the ligature was an improper measure, and must have promoted the occurrence of sphacelus. It seems also probable, from the account, that the vein was likewise tied; another serious and objectionable proceeding. Besides, it is worthy of notice, that the case was a wound of the axillary artery, attended with a copious effusion of blood in the cellular membrane. In all examples of this kind, gangrene is more readily induced, than when the case is merely a circumscribed aneurismal tumor. (See *Œuvres Chir. de Desault, par Bichat*, t. ii. p. 553.) As for Pelletan's example, it hardly deserves recital, because the operation in fact was not achieved. His colleagues objected to dividing the pectoral muscle; a random thrust was made with a needle and ligature; and the artery was not included. (See *Clinique Chir.* t. ii. Obs. 7, p. 49.)

In a case of axillary aneurism, which had actually burst, and the hemorrhage from which could

only be stopped by pressing the artery against the first rib, the late Mr. Thomas Keate, surgeon-general, practised the following operation, which was attended with complete success. His plan was to take up the artery, above the diseased and ruptured part, in its passage over the first rib. Accordingly he made an incision obliquely downwards; divided the fibres of the pectoral muscle that were in his way; and, when he came to the artery, passed a curved, blunt-pointed silver needle, armed double, as he conceived, under the artery, and tied two of the ends. After a careful examination, finding that the artery pulsated below the ligature, he determined on passing another ligature higher up, and nearer to the clavicle: he therefore passed the needle more deeply, so as evidently to include the artery. In a few days the swelling of the arm began to subside, the wound suppurated, and the ligatures came away with the dressings. The arm afterwards recovered its feeling, and the patient regained, in a great measure, the entire motion of the shoulder, &c. (See *Med. Review and Magazine for 1801*.) This method is objectionable, inasmuch as it was a dive made with a needle, and attended with great danger of wounding and tying parts which should be left undisturbed.

Mr. R. Chamberlaine, of Kingston, Jamaica, took up the axillary artery below the clavicle, in a patient who had an aneurism in the left axilla, occasioned by a wound with a cutlass on the 5th of October, 1814. On the 10th of January, the tumor had considerably increased, and was less compressible than it had been when first seen by Mr. Chamberlaine. The operation was done on the 17th of January, 1815. "A transverse incision, of three inches in length, was made through the skin and platysma myoides, along and upon the lower edge of the clavicle, three finger-breadths from the sternal end of that bone, and terminating about an inch from the acromion scapulæ. This incision divided a small artery, which was immediately secured. A second incision, of three inches in length, was also made obliquely through the integuments over the deltoid and pectoral muscles, meeting the first nearly in the centre. The cellular membrane and fat, lying between them at the upper part, were now removed. The next step consisted in detaching the clavicular portion of the pectoralis major, and taking away the fat and cellular membrane lying over the subclavian vessels. The artery was now brought into view, and its pulsations made it clearly distinguishable from the contiguous parts." After several ineffectual efforts, Mr. Chamberlaine succeeded in conveying a ligature under it, by means of an eye-probe, curved for the purpose, and the point of which was brought up with the aid of a pair of forceps. On the 22nd of February, the wound was completely healed; the aneurismal tumor reduced to the size of a turkey's egg, and very solid; the arm smaller than its fellow, but its muscular power improving. (See *Medico-Chir. Trans.* vol. vi. p. 128, &c.) Mr. Chamberlaine expresses his conviction, that the operation would have been much facilitated had he been furnished with the instruments described in Mr. Ramsden's work for passing the ligature under the artery: a still better invention, however, for passing a ligature under a deep artery, is the needle constructed by Mr. Weiss, surgeons' instrument-maker in the Strand. An engraving and description of this valuable instru-

ment may be found in the *Edin. Med. and Surgical Journal*, No. 76.

Mr. Hodgson's directions for the performance of this operation are very clear: A semilunar incision through the integuments, which is to have its convexity downwards, and to begin about an inch from the sternal end of the clavicle, being continued towards the acromion for the extent of three or four inches, so as to end near the anterior margin of the deltoid muscle, without reaching into the space between the deltoid and pectoral muscle, in order to avoid wounding the cephalic vein. This incision will expose the fibres of the pectoral muscle, which are now to be divided in the direction and extent of the external wound. The flap is then to be raised, by dividing the loose cellular tissue which connects the pectoral muscle to the parts underneath it. The pectoralis minor will now be seen crossing the inferior part of the wound; and, by introducing his finger between the upper edge of this muscle and the clavicle, the surgeon may feel the pulsations of the axillary artery. Here one of the cervical nerves lies above, but in contact with, the artery; the other nerves are behind it. In the dead subject, the axillary vein is situated below it: but in the living the vein is distended, and conceals the artery. The cellular tissue, connecting these parts, is to be separated by careful dissection, or by lacerating it with a blunt instrument. A ligature having been drawn under the artery with an aneurism needle, the ends of the cord are to be raised, and a finger passed down, so as to compress the part surrounded by the ligature. If the artery be included, the pulsation in the aneurism will immediately cease. This precaution is highly necessary, lest one of the cervical nerves should be tied instead of the artery. (See *Hodgson, On Dis. of Arteries*, &c. p. 362.)

When an aneurism extends a certain way inwards, or towards the trachea, the operation below the clavicle becomes impracticable; and it is now requisite to make the incision above that bone, and take up the subclavian artery at the point where it comes out from between the scaleni muscles, and lies on the flat surface of the first rib.

In the dead subject, without any tumor under the clavicle, this operation is easy enough; but in a living patient, and particularly in one whose neck is short, the difficulty is much increased by a large axillary aneurism, for then the clavicle is sometimes so much elevated, and the artery lies so deeply, that a ligature can hardly be carried under it without a particular needle for the purpose. This was the case in an attempt which I once saw made by Mr. Ramsden to tie the artery, and in which one of the cervical nerves, affected by the pulsation of the artery, was mistaken for it, and tied, so that the aneurism soon afterwards burst, and a fatal hemorrhage arose. Hence, the advice given by my friend Mr. Hodgson, always to operate in this case while the tumor is small, cannot be too well remembered. The direction given by Mr. Liston is also important; indeed, it is given by Mr. Hodgson in relation to the operation below the clavicle, and may be said to apply to all operations for the cure of aneurism. It is one which Dupuytren always particularly insisted upon; namely, "before tightening the ligature, try the effect of compression with the fingers on the pulsation, as by taking this precaution (says

Mr. Liston) I saved myself and my patient the pain of tying the nerve, which I got hold of in my first operation, in place of the artery." (*Lancet*, No. 195, p. 234.) The chief difficulty in the operation is that of passing the ligature round the artery; but, it may be done either with an ingenious needle, which Mr. Ramsden has described, and which is exactly similar in principle to Desault's *aiguille à ressort*, or with the still preferable instrument constructed by Weiss. Another very ingenious contrivance for tying deep arteries has also been recently proposed by Dr. Prevost, of Geneva. (See *Edin. Med. and Surgical Journ.* No. 79.) The instruments used by Dr. Mott, when he took up the *arteria innominata*, will be presently noticed.

In order to avoid the inconveniences of the needles ordinarily used for conveying ligatures under deep arteries, Desault (says Bichat) invented "*une aiguille à ressort*," composed of a silver tube, or sheath, which was straight at one end, and bent at the other in a semicircular form. This sheath enclosed an elastic wire, the projecting extremity of which was accurately fitted to the end of the sheath, and perforated with a transverse eye. The instrument was passed under the artery, and, as soon as it had reached the other side of the vessel, the sheath was kept fixed, while an assistant pushed the elastic wire, which, rising from the bottom of the wound, presented the aperture or eye to the surgeon, who now passed the ligature through this opening. The wire was next drawn back into its sheath again, and the whole instrument brought from beneath the artery, by which means the ligature was conveyed under the vessel. (See *Œuvres Chir. de Desault, par Bichat*, t. ii. p. 560.) Another very ingenious method of passing the ligature under the artery, is that practised by Mr. Key; but, as the comprehension of it is difficult without the plate, I shall here merely refer to that gentleman's description of it. (See *Med. Chir. Trans.* vol. xiii. p. 10.)

The invention of the foregoing instruments effects a material diminution in the difficulty of taking up the subclavian artery from above the clavicle; nor can it be wondered, that without such assistance, the operation should have baffled even so skilful a surgeon as Sir A. Cooper. (See *Lond. Med. Review*, vol. ii. p. 200.)

The following example is the first in which the operation of applying a ligature to the subclavian artery above the clavicle was ever accomplished.

John Townly, a tailor, aged thirty-two, addicted to excessive intoxication, of an unhealthy and peculiarly anxious countenance, was admitted into St. Bartholomew's Hospital on Tuesday, the 2nd of November, 1809, on account of an aneurism in the right axilla. The prominent part of the tumor in the axilla was about half as big as a large orange, and there was also much enlargement and distention underneath the pectoral muscle, so that the elbow could not be brought near the side of the body.

"The temperature of both arms," says Mr. Ramsden, "was alike, and the pulse in the radial artery of each of them was correspondent. After the patient had been put to bed, some blood taken from the left arm, and his bowels emptied, his pulse, which, on his admission, had been at 130, became less frequent; his countenance appeared more tranquil; and he experienced some remission

of the distressing sensations in the affected arm : this relief, however, was of short duration."

The pulsation of the radial artery of the affected arm gradually became more obscure, and soon after either ceased, or was lost in the œdema of the forearm and hand. On the evening of the twelfth day, a dark spot appeared on the centre of the tumor, surrounded by inflammation, which threatened a more extensive destruction of the skin. A further postponement of the operation being deemed inadmissible, Mr. Ramsden performed it the next day in the following manner : a transverse incision was made through the skin and platysma myoides, along and upon the upper edge of the clavicle, about two inches and a half in length, beginning towards the outer border of the trapezius, and terminating about half an inch within the outward edge of the sterno-cleido-mastoideus muscle. "This incision divided a small superficial artery, which was directly secured. The skin, above the clavicle, being then pinched up between my own thumb and finger and those of an assistant, I divided it from within, outwards and upwards, in the line of the outward edge of the sterno-cleido-mastoideus muscle, to the extent of two inches.

"My object, in pinching up the skin for the second incision, was to expose at once the superficial veins, and, by dissecting them carefully from the cellular membrane, to place them out of my way, without wounding them. This provision proved to be useful, for it rendered the flow of blood during the operation very trifling comparatively with what might otherwise have been expected ; and thereby enabled me with the greatest facility to bring into view those parts which were to direct me to the artery.

"My assistant having now lowered the shoulder, for the purpose of placing the first incision above the clavicle (which I had designedly made along and upon that bone), I continued the dissection with my scalpel, until I had distinctly brought into sight the edge of the anterior scalenus muscle, immediately below the angle, which is formed by the traversing belly of the omo-hyoideus, and the edge of the sterno-cleido-mastoideus ; and having placed my finger on the artery, at the point where it presents itself between the scaleni, I found no difficulty in tracing it without touching any of the nerves to the lower edge of the upper rib, at which part I detached it with my finger nail for the purpose of applying the ligature.

"Here, however, arose an embarrassment, which (although I was not unprepared for it) greatly exceeded my expectation. I had learned, from repeatedly performing this operation, many years since, on the dead subject, that to pass the ligature under the subclavian artery, with the needle commonly used in aneurisms, would be impracticable ; I had, therefore, provided myself with instruments of various forms and curvatures to meet the difficulty, each of which most readily conveyed the ligature underneath the artery, but would serve me no further ; for, being made of solid materials, and fixed into handles, they would not allow of their points being brought up again at the very short curvature which the narrowness of the space between the rib and the clavicle afforded, and which, in this particular case, was rendered of unusual depth, by the previous elevation of the shoulder by the tumor.

"After trying various means to overcome this difficulty, a probe of ductile metal was at length handed me, which I passed under the artery ; and bringing up its point with a pair of small forceps, I succeeded in passing the ligature, and then tied the subclavian artery at the part where I had previously detached it for that purpose. The drawing of the knot was unattended with pain, the wound was closed by the dry suture, and the patient was then returned to his bed." (See *Practical Obs. on the Sclerocele, &c. to which are added four Cases of Operation for Aneurisms*, p. 276, &c.)

Immediately the artery was tied, the pulsation of the swelling ceased ; the arm of the same side continued to be freely supplied with blood, and was even rather warmer than the opposite arm ; the operation, which was severe from the length of time it took up, was followed by considerable indisposition ; the patient died about five days after its performance ; after the artery had been tied, the œdema of the arm and the aneurismal tumor partly subsided ; and on examination after death, nothing but the vessel was found included in the ligature.

In Mr. Ramsden's publication are descriptions of instruments which will be of great service to any future performer of this operation. The chief one is a needle, resembling that which was invented and used by Desault, and of which I have already endeavoured to give an idea. By means of this or other instruments already specified, I conceive, that the main difficulty of the operation will in future be avoided. Had Mr. Ramsden had its assistance, his patient would have been detained a very little time in the operating theatre, and the event of the case might have been completely successful. Having witnessed all the circumstances of the case, the inference that I drew from them was, that, if the operation could have been done in a moderate time, which now seems practicable with the aid of some kind of *aiguille à ressort*, or even without it in most examples, the case in all probability would have ended well. The preceding case is particularly memorable, as being the first instance in which the subclavian artery was scientifically tied, without any random thrust of a needle, and without the inclusion of any part besides the artery in the ligature. It furnished encouragement to repeat the experiment ; held out the hope, that axillary aneurisms might be cured as well as inguinal ones ; and confirmed the competency of the anastomosing arteries to nourish the whole upper extremity, when the subclavian is tied where it emerges from behind the anterior scalenus muscle.

In the year 1811, the subclavian artery was tied in the London Hospital, in a case of axillary aneurism, by Sir W. Blizard, who found no difficulty in getting the ligature under the artery with a common aneurism-needle. A single ligature was applied. At first, hopes of recovery were entertained ; but the patient, who was old and debilitated, afterwards sunk, and died on the fourth day. (See *Hodgson's Treatise*, p. 375.)

In the year 1815, Mr. Thomas Blizard tied the subclavian artery in the same Hospital. The case was an aneurism in the left axilla, and, like all the other examples of this kind upon record, was attended with great pain in the tumor and limb. There was no pulse in the left radial artery,

though there was scarcely any difference in the temperature of both arms. "An incision, about three inches in length, was made through the integuments at the root of the neck, on the acromial side, and parallel with the external jugular vein. The platysma myoides being divided, the cellular membrane was separated with the finger, until the pulsation of the subclavian artery was felt where the vessel passes over the first rib. The finger being pressed upon this part of the artery, the cellular sheath investing it was carefully opened with the point of a knife. A ligature was then conveyed underneath the artery, by means of a common aneurism-needle, with the greatest facility." As soon as the ligature was tied, the pulsation in the tumor ceased. On the second day after the operation, the left arm began to have more feeling, and was as warm as the right. However, difficulty of breathing, twitchings, delirium, &c., afterwards ensued, and the patient died on the evening of the eighth day, previously to which event the ring and middle fingers turned black. On opening the body, the pericardium exhibited the effects of a high degree of inflammation, and the heart was covered with flakes of lymph, its posterior surface being of a deep red colour. The inner membrane of the ascending aorta was of a bright scarlet hue, much diseased, and studded with white patches. A reddish appearance was also noticed in the lining of the right carotid, left subclavian, and even the abdominal aorta. The boundaries of the aneurismal tumor were in a state of sphacelation. These are all the circumstances which I wish here to notice; but more particulars may be perused in Mr. Hodgson's work, p. 602.

In some cases upon record, no difficulty was experienced in passing the ligature under the artery with a common aneurism-needle, a circumstance which must have depended upon the space between the clavicle and the first rib having been less deep in these instances than the two which fell under my own observation, or in others which occurred in the practice of Dr. Colles, Sir Astley Cooper, and Mr. Liston. (See *Lond. Med. Review*, vol. ii. p. 200; and *Edin. Med. and Surg. Journal*, January, 1815, No. 64.) In Mr. Key's case, "the depth of the angle in which the artery was enclosed, rendering it impossible to pass a ligature under it, about three quarters of an inch of the clavicular portion of the sterno-mastoid was divided, which afforded sufficient room, and rendered the concluding part of the operation easy; the artery became readily exposed to view, and an armed aneurismal needle was passed with facility under it." (*Med. Chir. Trans.* vol. xiii. p. 5.) It is an observation made by Dupuytren, that in persons who have long necks, the subclavian artery is more superficial than in others whose necks are short. The size and situation of the tumor will also make a considerable difference; for if it be large, and placed a certain way towards the shoulder, it may raise the clavicle a good way from the first rib, and increase the difficulty of the operation.

In Dr. Colles's first case, the artery was tied before it reached the scaleni muscles, as the tumor, which was in the right subclavian artery, extended from the sternal origin of the sterno-mastoid muscle along the clavicle, a little beyond the arch of that bone, and rose nearly two inches above it, in a conical form, the apex of the cone

being situated at the outer edge of the foregoing muscle. After a tedious dissection, it was found, that only a quarter of an inch of the artery was sound, and on this portion the ligature was placed. Great difficulty was encountered in passing it round the artery, and the pleura was supposed to have been slightly wounded. Before tightening the ligature, the breathing became laborious, and the patient complained of oppression about the heart. These symptoms, indeed, were so violent, that it was judged prudent not immediately to tighten the ligature. On the fourth day, however, the artery was constricted, when the pulse at the wrist ceased, the patient not seeming to suffer much from what had been done. The patient then went on pretty well till the ninth day, when he was seized with a sense of strangling, and pain about his heart; and becoming delirious, died in nine hours after the beginning of this attack. On dissection, the aorta was found diseased, and the disease extended into the subclavian artery.

In another instance, Dr. Colles tied this vessel at the point where it emerges from between the scaleni muscles, without any particular difficulty. The operation, however, was soon followed by a train of severe symptoms, delirium, and mortification; the patient dying on the fifth day. (See *Edin. Med. and Surg. Journ.* January, 1815.)

The first case in which complete success attended the operation of tying the subclavian artery, where it first comes from behind the anterior scalenus muscle, was that under the care of Dr. Post, of New York. The patient was a gentleman, with an aneurism in the left axilla. Dr. Post performed the operation on the 8th of September, 1817, in the following manner:—"An incision, commencing at the outer edge of the tendon of the mastoid muscle, was carried through the integuments about three inches in length, in a direction deviating a little from a parallel line with the clavicle. This divided the external jugular vein, the bleeding from which required a ligature for its suppression; and, in proceeding with the operation, three or four arterial branches were cut, which it was also necessary to secure. The subclavian artery was then sought immediately on the outside of the scaleni muscles, and was easily laid bare. Passing over the artery at this place, in contact with it, were three considerable branches of nerves, running downwards towards the chest, from the plexus above. These were separated, and a ligature passed under the artery, with great facility, by the instrument, well adapted to this purpose, invented by Drs. Parish, Hartshorn, and Hewson, of Philadelphia. On tying the ligature all pulsation ceased in the limb." In the afternoon, the temperature of the limb was observed to be rather higher than that of the other arm. On the 17th of September, the aneurismal tumor burst, and about three ounces of dark coagulated blood were discharged. On the 26th, the ligature came away from the subclavian artery. Oct. 11. the wound was entirely healed; and on the 16th of the same month the patient required no further attendance, his only complaints being now a little occasional pain in the fingers, and a superficial sinus at the part where the tumor burst. (See *Med. Chir. Trans.* vol. ix. p. 185, &c.)

In Europe, the first axillary aneurism cured by taking up the subclavian artery from above the

clavicle, was that in which Mr. Liston was the operator, on the 3rd of April, 1820. The particulars of the case prove the risk there always is of tying one of the axillary nerves, instead of the artery, unless great caution be employed; and, in fact, Mr. Liston himself first passed the ligature under a nerve, and would have tied it, had he not wisely tried what effect constricting the included part would have upon the pulsation of the tumor; a criterion that was never neglected by Dupuytren in operations for aneurism. As the subclavian artery seemed diseased at the point where it emerged from behind the anterior scalenus, Mr. Liston cautiously divided this muscle to about its middle, so as not to injure the phrenic nerve. At length, with the aid of an aneurism-needle, he passed a strong round silk ligature under the artery, and, laying hold of the loop with a small hook, withdrew the needle. In consequence of the great depth of the artery, the knot could not be made with the fingers; but, with the assistance of a kind of forceps, each extremity of which had a little notch in it, the business was accomplished. (See *Edin. Med. and Surgical Journ.* No. 64.)

When the subclavian artery has emerged from behind the anterior scalenus muscle, it passes obliquely over the flat surface of the first rib, with which it is in immediate contact. The cervical nerves are situated above and a little behind the artery: the subclavian vein passes before it, and underneath the clavicle. If the finger be passed down the acromial margin of the anterior scalenus muscle the artery will be found in the angle, formed by the origin of that muscle from the first rib. The shoulder being drawn down as much as possible, the skin is to be divided, immediately above the clavicle, from the external margin of the clavicular portion of the mastoid muscle to the margin of the clavicular insertion of the trapezius. I think, with Mr. Hodgson, that no advantage whatever can be gained by cutting the clavicular attachment of the sterno-cleido-mastoideus. The exposed fibres of the platysma myoides are now to be carefully divided, without wounding the external jugular vein, which lies immediately under them, near the middle of the incision, and should be detached, and drawn towards the shoulder with a blunt hook. The cellular membrane, in the middle of the incision, is then to be cut, or separated with the finger, until the surgeon arrives at the acromial edge of the anterior scalenus. He passes his finger down the margin of this muscle, until he reaches the part where it arises from the first rib, and in the angle formed by the origin of the muscle from the rib he will feel the artery. The ligature is now to be conveyed under the vessel with an aneurism-needle, or that recommended by Desault. (*Hodgson, On Diseases of Arteries, &c.* p. 376, &c.)

[The result of the ligature of the subclavian artery in the third part of its course, for spontaneous axillary aneurism, is as follows:—of 45 cases, there were 23 cures, and 22 deaths. This result was so unfavourable, that I have analysed the causes of death, and find them as follows:—

Inflammation within the chest	9
Suppuration of sac	6
Hemorrhage	2
Gangrene of arm	1
General gangrene	1
Not stated	3

In 1819, Baron Dupuytren took up the left subclavian artery in the second part of its course, for the cure of an axillary aneurism, following a stab. This eminent surgeon used to consider this vessel as having three different portions; the first, extending from its origin from the aorta to the point where it passes between the scaleni; the second, from its entrance between the scaleni to the point of its quitting the interspace between them; the third, from the latter point to the upper surface of the first rib. This third portion of the course of the subclavian artery, which in individuals whose necks are long and slender, and whose shoulders are low and thin, is not far beneath its skin, is, on the other hand, very deeply placed in persons whose necks are thick and short, and whose shoulders are covered with a good deal of flesh. In particular, this portion of the vessel is also deeply seated, when the clavicle is pushed up by a tumor in the axilla. Dupuytren's patient was in these latter circumstances; and besides the difficulty which they created to the ligature of this portion of the artery, Dupuytren reckoned that he should have had a good deal of trouble in separating the artery from the brachial plexus of nerves, which, however, in this situation, in reality lie above the vessel, the lowermost one alone lying close above it. Now, Dupuytren conceived that the second part of the course of the artery presented the advantage of the vessel passing alone between the scaleni, entirely separated from the subclavian vein, which ran in front of the anterior scalenus muscle, and also from the brachial plexus, the nerves of which lay backwards and outwards; consequently, by taking the anterior scalenus muscle as a guide he judged that the artery might be tied, without risk of including any nerve in the ligature.

Governed by these reflections, Dupuytren made an incision on the left side, and at the lower part of the neck, from above downwards, and from within outwards. By this the skin, platysma, and subcutaneous cellular tissue were divided, together with three small vessels, which were immediately secured. In the continuation of the operation, the cellular tissue and absorbent glands contiguous to the artery and brachial plexus were arrived at. The external border of the anterior scalenus was sought for, and this muscle completely cut through near its insertion, with the aid of a probe-bistoury. The artery was now exposed, and its pulsation readily stopped by the pressure of a finger passed to the bottom of the wound. A silver director, bent in the form of a quarter of a circle, was passed under the artery; and an eye-probe, armed with a ligature composed of three silk threads, conducted along the groove of the director, and withdrawn from the opposite side. Care was now taken to ascertain that the ligature was really under the artery by pulling at each end of it, and at the same time placing the forefinger on the vessel above it. In this manner it was found that the pulsation of the artery was completely stopped. This proceeding, repeated several times, was observed not to give the least pain; a proof that no nerve was included in the ligature. The artery was now tied; the wound brought together; and the limb placed on a pillow, and covered with bags filled with warm sand. This case proved successful. By the sixty-eighth day the tumor was reduced to one-fifth of its original size. The heat,

sensibility, and muscular powers of the limb were entirely re-established. In it, as in all limbs whose principal artery has been tied, the arteries did not pulsate, though blood circulated freely through them. This fluid in passing through numerous and minute anastomoses, from the upper to the lower portion of the limb, seemed to Dupuytren to be no longer within reach of the power of the heart. Between two and three years after the operation, an abscess formed in the axilla and burst. Dupuytren enlarged its opening, and a great deal of pus, blended with old coagula, was discharged. This was soon followed by a perfect cure. (See *Leçons Orales de Cliniq. Chir.* t. iv. p. 524—535.) The reasons assigned by Dupuytren for choosing this method of operating, appear to me not so good as one which, I believe, is the only valid ground for taking up the subclavian in the second part of its course, viz. the extension of the tumor too far inwards to admit of the ligature being applied at the point where the artery emerges from behind the anterior scalenus, close behind the tubercle of the first rib. This point can always be reached with facility, by tracing the outer edge of that muscle downwards, whatever may be the conformation of the neck or the height of the shoulder. The phrenic nerve, be it remembered, would also be considerably exposed to injury in Dupuytren's method, which therefore seems to me eligible only under the circumstances already specified.

With respect to tying the subclavian artery on the tracheal side of the scalenus, I have stated that it was performed by Dr. Colles, and the event fatal. Descriptions of the operation may be found in Mr. Hodgson's work, p. 382. When I consider the manner in which the subclavian artery, before it passes behind the anterior scalenus, is surrounded by parts of great importance, I can scarcely bring my mind to think that the measures requisite for taking up the vessel in this situation will ever leave the patient much chance of recovery. "Between the aorta and scaleni muscles (says Mr. A. Burns), the subclavian arteries are connected with several important vessels and nerves. They are in the vicinity of the nervus vagus, of the recurrent laryngeal nerve, of the sympathetic nerve, of the phrenic nerve, and the subclavian vein; and, on the left side, the subclavian artery is intimately connected with the termination of the thoracic duct. These parts are all grouped together in a very narrow space, and the perplexity of their dissection is further increased by the interlacement of the different nerves with one another. The natural connections of these parts are best shown by merely raising the external extremity of the sterno-mastoid muscle. If this be done, the nervus vagus will be brought into view, lying on the forepart of the subclavian artery, almost directly behind the sternal end of the clavicle; and exactly opposite to the nervus vagus, but behind the artery, the lower cervical ganglion of the sympathetic nerve will be brought into view. The recurrent nerve, on the right side, hooks round the subclavian artery, and, in its course towards the larynx, ascends along the tracheal side of the sympathetic nerve. On the left side, it twines round the arch of the aorta, and, in mounting upward, is interposed between the subclavian artery and œsophagus. The subclavian vein lies anterior to the artery, and, in the

collapsed state, sinks nearer to the thorax;" but, when distended in the living body, it overlaps the artery. The thoracic duct enters the subclavian vein about the eighth of an inch nearer to the acromion than the point where the internal jugular vein empties itself into the subclavian vein. The termination of the thoracic duct is situated between the sternal and clavicular portions of the sterno-mastoid muscle. (*A. Burns, On the Surgical Anatomy of the Head and Neck*, p. 28.)

[The subclavian has been ligatured on the tracheal side of the scalenus in seven cases, and all have proved fatal. In six from hemorrhage, and in one from diffuse inflammation within the chest. The accompanying table includes all the cases in which this operation has been performed.]

SURGEON.	SEX.	AGE.	DATE OF DEATH.	CAUSE OF DEATH.
COLLES.	m.	33	4th day.	Hemorrhage.
MOTT.	f.	21	18th "	"
HAYDEN.	f.	57	12th "	"
O'REILLY.	m.	39	13th "	"
PARTRIDGE.	m.	38	4th "	Pericarditis and pleurisy.
LISTON.	m.		13th "	Hemorrhage.
LISTON.	m.		36th "	"

The great danger in these cases is from hemorrhage, depending as this does on the anatomical relations and connections of the artery, which no skill on the part of the operator can in any way lessen. This operation ought, in my opinion, to be banished from surgical practice.]

Axillary aneurisms are sometimes attended with fluctuation, in consequence of the blood becoming effused in the cellular tissue, and the pulsation in the deeper part of the swelling is then concealed. In such a case, Dupuytren once suspected the disease to be a chronic abscess, and made an exploratory puncture into the swelling; but a gush of blood made him promptly withdraw the knife and close the wound. The puncture healed up. Dupuytren wished to have tied the subclavian artery, but he was opposed by one of his colleagues; and, in the end, a point of the skin sloughed, hemorrhage took place, and the patient died. (*Clin. Chir.* t. iv. p. 520.)

A case, in which an axillary aneurism, unattended with pulsation, was punctured, and the child bled to death, is recorded. (See *Med. Chir. Journ.* vol. iv. p. 78.)

Mr. Guthrie observes, whenever an aneurismal tumor in the neck is accompanied by an alteration of the sterno-clavicular articulation, the case is clearly unfit for any operation, except that suggested by Brasdor, even if any operation at all be admissible. (See *Guthrie, On the Arteries*, p. 397.) The same, he adds, may be said of any case of aneurismal swelling, either internal or external to that articulation, in which the stethoscope, applied on the sternum in the course of the arteria innominata, or the arch of the aorta, indicates disease. A swelling at the root of the carotid is more likely to be an aneurism of the arch of the aorta or of the innominata, than of the carotid itself, and the stethoscope will remove all doubt. In one case of subclavian aneurism, where the tumor left no room

for the application of a ligature on the tracheal side of it, and where there was great reason to suspect that the arteria innominata was itself enlarged, Baron Dupuytren took up the axillary artery on the 12th of June, 1829, in the Hôtel Dieu. The patient was placed in the recumbent posture, with the right arm raised from the side. An incision was begun near the inner end of the clavicle, two finger-breadths below it, and extended outwards nearly parallel to that bone for about three inches. The fibres of the great pectoral muscle, and then the upper third of the lesser pectoral, were divided. The axillary artery having been next separated from the vein and brachial plexus of nerves, a ligature was passed under it, with an eye-probe, and tightened, the doing of which occasioned no pain. In the course of the operation, which lasted thirty-five minutes, several arterial branches were cut and secured. Immediately after the axillary artery had been tied, the pulsations of the tumor became stronger and irregular, but soon returned to their former strength; simple dressings were applied to the wound, and a bladder of ice to the swelling. An anodyne draught was also exhibited ten hours after the operation; the pulse was strong and under ninety in the minute. Some blood was now taken from a vein in the arm. On the 13th of June, the patient was feeble, and complained of restlessness and want of sleep. The pulsations in the tumor had not sensibly lessened, but the tension seemed diminished; and the limb retained its natural temperature. On the 16th, the pulse was only eighty, and the tumor and throbbing of it had manifestly diminished. Venesection was afterwards practised several times, and about six ounces of blood came away from the wound. The patient died on the 20th, and was supposed to have been too much lowered by the rigorous antiphlogistic treatment. The origin of several large arterial branches from the subclavian near the tumor, is regarded as a great cause of the little success which this method of operating promises, as applied to subclavian aneurisms; yet it deserves notice, that in the case before us, the vertebral, internal mammary, and inferior thyroid branches were all found obliterated. This, according to Dupuytren, must frequently happen, when the aneurism has attained a certain size; and, therefore, he infers, that their presence should not deter a surgeon from applying a ligature between the tumor and the capillaries. No doubt, the diseased state of the right lung, and the morbid changes in the aorta, as observed after death, must have had a very unfavourable influence. (*Clin. Chir.* t. iv. p. 594.) Dupuytren publicly declared, that the preceding case would not deter him from repeating a similar operation in the same kind of case. (P. 611.)

LIGATURE OF THE ARTERIA INNOMINATA.

In certain cases of subclavian aneurism, it has been proposed to tie the arteria innominata. In the dead subject, Mr. Allan Burns applied two ligatures to it; and after cutting through the vessel in the interspace, he injected the aorta, when the injection was found to pervade the anastomosing vessels of the right arm, and all those of the head. But notwithstanding this fact, and others noticed by Mr. Hodgson, tending to show the probability that a ligature upon the arteria innominata would not prevent the arm and head from receiving an

adequate supply of blood, other objections were made to the practice. The principal of these were founded upon the difficulty of the operation in the living body; the inflammation likely to be excited by it in neighbouring important organs; the danger of hemorrhage from the adhesion of the vessel being likely to be broken by the force of the circulation; and the equal practicableness, in most cases, of tying the subclavian artery on the tracheal side of the scalenus.

Dr. Mott, of New York, impressed with the value of Mr. Allan Burns' remarks upon this subject, has, ever since he became acquainted with them, maintained in his lectures the propriety of attempting to tie the arteria innominata, under particular circumstances of subclavian aneurism. At length Dr. Mott put this new operation to the test of experience in the New York Hospital, on the 11th of June, 1818. The case was a subclavian aneurism on the right side; and the patient, a sailor, aged fifty-seven, to whom seventy drops of tinct. opii were first given. Dr. Mott began the first incision directly over the swelling above the clavicle, extending it along this bone, and ended it at the trachea, just above the upper portion of the sternum. Here he commenced the second incision of about the same length as the first, and reaching along the inner margin of the sternocleido-mastoideus. Dr. Mott next detached the skin from the subjacent platysma myoides, cut through the latter, and cautiously divided the sternal portion of the mastoid muscle, in the direction of the first incision. The anterior jugular vein now presented itself close to the swelling, and adherent to it; a circumstance that rendered the subsequent part of the operation very difficult. After detaching a portion of the latter vein from its connection, Dr. Mott cut through the sternohyoideus and sterno-thyroideus, and turned them back over the trachea. The carotid was now exposed a few lines above the sternum; and after he had separated the par vagum and internal jugular vein from it, they were drawn towards the outer side of the neck. Dr. Mott then laid bare the subclavian artery, which part of the operation he chiefly accomplished with the handle of the scalpel, as there was nothing to be separated but cellular membrane. The subclavian artery was found to be very much enlarged and diseased; and, as Dr. Mott recollected that this state of the vessel had seemingly hindered its successful closure, in the example operated upon by Dr. Colles, of Dublin, he decided to take up the arteria innominata itself. In detaching the cellular membrane from the lower surface of the subclavian artery, a small branch, situated about half an inch from the innominata, was injured, and the wound was six or eight times filled with blood from it. The hemorrhage was soon suppressed, however, by means of a little pressure. Had not the bleeding been so easily stopped, Dr. Mott would have concluded, from the situation of the vessel, that it was the internal mammary; but, if it were not this branch, he conceives it must have been an artery not regularly originating in this situation; perhaps the superior intercostal.

Dr. Mott continued the operation with a small round-ended sharp scalpel, until he came to the division of the arteria innominata, which great vessel he traced below the sternum; and after freeing it from all the cellular membrane with

the handle of the scalpel, and drawing aside the recurrent and phrenic nerves, he tied it with a round silk ligature, about half an inch from its bifurcation.

On account of the difficulty of tying large arteries in a deep small wound, Dr. Mott recommends a set of instruments, invented for the purpose, in Philadelphia, by Drs. Parish, Hartshorn, and Hewson; consisting, 1st. Of several blunt-pointed needles, of various sizes and curvatures, furnished with an eye at each end, and calculated at one end to screw into a strong handle. 2ndly. Two strong instruments, with handles, having at one end an eye, or hole; they resemble those sometimes used for applying a ligature to the tonsils. 3rdly. A small round-pointed scalpel. 4thly. A small hook fixed in a strong handle. (*Parish, in Eclectic Rep.* vol. iii. p. 229.) After Dr. Mott had introduced the ligature into the eye of one of the above-described needles, and screwed the needle into a handle, he pressed with its convexity the cellular membrane and pleura carefully downwards, while he carried it from below upwards round the artery. As the point now appeared on the other side of the vessel, the above-mentioned hook was passed into its eye, and the handle unscrewed from the other end of it, when it was easily drawn out from under the artery, and the ligature left under the vessel. In this part of the operation, Dr. Mott urges the necessity of being particularly attentive to two important circumstances; one, is, to convey the ligature round the artery from below upwards, as the only way to prevent injury of the pleura; and the other is, to fix the hook in the eye of the needle before the handle is unscrewed from its other end, because, after this has been done, the needle loses all steadiness, and it is then difficult to get the hook into the eye.

Dr. Mott now made a noose, pressed it with the forefinger down to the artery, and tightened it very gradually, in order not to stop the flow of blood through the vessel all at once. A moderate constriction was kept up some seconds, so that the effect of the ligature upon the heart and lungs might be observed; and as no disturbance was produced in the functions of these organs, Dr. Mott tightened the ligature, and stopped the current of blood through the vessel. At this instant, the pulsation of the right temporal and radial arteries ceased. The noose was tightened still more with the above-mentioned ligature irons, and then a second knot was made. Dr. Mott was greatly pleased at finding his patient's countenance remain perfectly unchanged, and no complaint made of pain in any other part. Immediately after the ligature had been applied, the aneurismal swelling lost one-third of its size, and the clavicle could be felt through its whole extent. The divided muscles and detached skin were now brought into their natural situation; the wound closed with three sutures and adhesive plaster, and a compress applied. In the operation, three small arteries were tied: the first lay under the sternum, and seemed to be a branch of the internal mammary; the second was a descending branch of the superior thyroideal; and the third a branch of the inferior thyroideal. From two to four ounces of blood were lost, most of which came from an injured small branch of the subclavian. The operation took up about an hour. The curved spatulæ,

recommended by Dr. Colles, were found very useful for holding the carotid and par vagum aside, while, by their uniform pressure, they materially assisted in restraining the effusion of blood from small vessels, and, as taking up little room, were infinitely more convenient in a deep narrow wound than the fingers of an assistant.

The day after the operation, the veins of the right forearm and hand had a turgid appearance. When the circulation in them was promoted by pressure, they became empty for some distance above the pressed part, but filled again immediately the pressure was removed; a circumstance that seemed to show that the circulation in this arm, notwithstanding the ligature of the arteria innominata, still went on with great celerity, though no pulse could be felt in the brachial and radial arteries. On the contrary, the pulse was very plain in the front branch of the temporal artery, just above the outer angle of the orbit. The left external carotid beat with unusual force. In a few days, however, the pulse became perceptible again at the right wrist.

My limits will not allow me to enter into all the details of this interesting case: suffice it to mention that the patient suffered considerable febrile disturbance at some periods after the operation, and it was necessary twice to have recourse to venesection. He was also afflicted with a severe cough. The discharge from the wound was copious and fetid. The main ligature separated on the fourteenth day. On the twentieth day, the patient was sufficiently recovered to walk in the garden. On the twenty-first day, the wound was almost closed; the patient could move his right arm with the same facility as his left, and he was gaining such strength, that no doubts were entertained about the successful result of the operation. On the twenty-third day, hemorrhage came on from the wound; it was stopped by the introduction of lint, and the employment of pressure. About twenty-four ounces of blood were lost, whereby the patient was so depressed, that the pulse was no longer distinguishable. On the twenty-fourth day, in the evening, he lost four ounces more blood; on account of his restlessness and the painful state of his arm, two grains of opium were administered to him. After one or more returns of bleeding, he died on the twenty-sixth day.

When the body was opened, no traces of inflammation or its consequences were found either in the arch of the aorta, the origin of the innominata, or the lungs. The aorta was now slit open longitudinally, and a probe then cautiously passed through it into the innominata, when the instrument went through the latter vessel into the cavity of the wound. The inner coat of the innominata was smooth and soft; but, about half an inch from the place where the ligature had cut through the vessel, marks of inflammation were noticed, and a coagulum adhered to the sides of the artery with considerable firmness; so that nature had probably endeavoured, by means of adhesive inflammation, to close the vessel, but had been prevented from completing the salutary process by the destructive ulceration. One portion of the parietes of the innominata was thickened by inflammation, and an anomalous branch, as large as a crow's quill, arose from this artery.

The ulcer was twice as extensive inwardly as it was superficially, reaching laterally to the trachea

and under the clavicle to the swelling. The tripod of great vessels, viz. the innominate, the subclavian, and the carotid, was destroyed by ulceration to the extent of about an inch, and the ends of both the last vessels opened into the wound. At this place, the pleura was considerably thickened by a layer of organized lymph.

The inner surface of the carotid was covered with a coagulum, and its coats so much thickened, that a probe could hardly be passed into it. The consolidation reached up to the division into the external and internal carotid. The subclavian was pervious as far as the situation of the disease. The diameter of the brachial and other arteries of the right arm was natural. The external mammary artery was enlarged, but not the internal. The clavicle was carious, and several lymphatic glands under it in a state of suppuration.

Though the result of the operation was unsuccessful, it proves, as Dr. Mott correctly remarks, some interesting points; namely, that tying an artery of such magnitude, and so near the heart, may be done without occasioning any disturbance either in the functions of the brain, the heart, the lungs, or the right arm.

The suppuration, which continually extended itself more and more deeply, is set down by Dr. Mott as the cause of the patient's death; for, as no bleeding took place for several days after the detachment of the principal ligature, he believes that this must have fulfilled its duty, and that the artery had been closed. (See *New York Med. and Surgical Register*, 1818, vol. i.)

The arteria innominata was also tied by Graefe, on the 5th of March, 1822, in the Clinical Hospital of the University of Berlin, on account of a subclavian aneurism. The carotid was exposed, and traced down to the innominate, to which a

ligature was applied by means of a blunt tenaculum constructed for the purpose, the vessel being tied about an inch from the curvature of the aorta, and two inches from the heart. As soon as the ligature was tightened, the pulsation of the arteries of the right arm, right carotid, and right temporal artery ceased; at the same instant, the throbbing of the aneurism stopped, and the tumor became flaccid. The constriction of the cord produced no disturbance of any function. The patient went on so well for several weeks afterwards, that no doubt was entertained of his recovery. However, when the wound was nearly healed, hemorrhage came on; and though it was suppressed, and hopes began to be again indulged, the bleeding recurred, and the patient died on the sixty-seventh day. Below the ligature the innominate was found closed with lymph. Graefe has written a distinct essay on the method in which the operation was done: the daily particulars of the case, and preparation from it, are placed in the Royal Anatomical Museum at Berlin. (See *Journ. de Chirurgie, von C. F. Gräfe, und Ph. v. Walther*, b. iii. p. 596, &c. b. iv. p. 587.) The ligature of the innominate is stated to have been lately done at Paris; but in this third example the patient also died of hemorrhage. (See *Dupuytren, Leçons Orales*, &c. t. iv. p. 611.) Of Mr. Wardrop's practice of tying the subclavian artery in aneurism of the arteria innominata itself, we shall presently speak.

[The innominate artery, as may be seen by the accompanying table, has been ligatured nine times, and in every instance with a fatal result. In eight of these cases the operation was performed for subclavian aneurism, in the remaining one (that of Hutin), for hemorrhage from the axilla, after ligature of the subclavian.

OPERATOR.	AGE.	RESULT.	REMARKS.
1. MOTT.	57	Died on 26th day.	Tied an inch below bifurcation. Ligature separated in fourteen days. Hemorrhage on twenty-fifth day, stopped by pressure. Recurred on twenty-sixth.
2. GRAEFE.		Died on 67th day.	Ligature separated in fourteen days. Died of hemorrhage.
3. HALL.		Died on 5th day.	Coats of artery were diseased, and were transfixed by the aneurism needle. Wound plugged without success.
4. DUPUYTREN.		Died.	Case referred to as occurring in the practice of Dupuytren.
5. NORMAN.		Died.	
6. BLAND.	31	Died on 18th day.	Hemorrhage on seventeenth and eighteenth days, shortly after separation of ligature.

In three other cases the operation has been commenced, but abandoned owing to unforeseen and unavoidable difficulties; and this by three of the most skilful operators that their respective countries can boast of; Messrs. Porter, Post, and Aston Key. In Mr. Porter's case, the aneurism occupied the whole of the posterior inferior triangle of the neck, being nearly six inches broad; as no pulsation was traceable in the vessels beyond the aneurism, it was useless to attempt the ligature on the distal side. On exposing the innominate, that vessel was found to be diseased, and it was not thought desirable to pass the ligature round it. In consequence of the exposure of the artery, however, the pulsation in the tumor gradually diminished, and at last ceased entirely, its bulk also becoming less.

In Mr. Key's case, in which it was impracticable to pass the ligature, it was found after death that the innominate was diseased, being dilated immediately after its origin into an oblong tumor, which occupied the whole of the artery. It is remarkable, that in this case, as in Mr. Porter's, inflammation seems to have taken place in the artery in consequence of the necessary handling to which it was subjected, and that the pulsation in the sac consequently diminished. The failure in deligating the artery appears then to be less disastrous in its consequences than success; for of the three cases just referred to, one was cured of the disease, the artery being obliterated by adhesive inflammation; and, in another, an attempt to set up this action appears to have been made,

the tumor becoming solid and ceasing to pulsate; whereas, in every case in which the vessel was ligatured, a fatal result speedily ensued. Under these circumstances, I think it is an operation that few prudent surgeons would again venture on performing.]

CAROTID ANEURISMS.

There is no part of the body where the diagnosis of aneurisms is more liable to mistake than in the neck. Here the disease is particularly apt to be confounded with tumors of another nature. I have already cited in this article examples in which aneurisms of the arch of the aorta so resembled those of the carotid, as to have deceived the surgeon who was consulted. A swelling of the lymphatic glands, or of the cellular substance which surrounds the carotid artery; an enlargement of the thyroid gland; and especially abscesses, may resemble an aneurism by the pulsations communicated to them from the neighbouring artery. On the other hand, aneurisms of long standing, which no longer throb, and the integuments over which are changed in colour, and likely to burst, may the more easily be mistaken by an inattentive practitioner for chronic abscesses, as the neck is remarkably often the seat of such diseases. (*Boyer, Maladies Chir. t. ii. p. 185.*)

Scarpa mentions one unfortunate patient, who was killed by a knife being plunged in a carotid aneurism, on the supposition that the case was an abscess. I need scarcely observe, that, by opening a carotid aneurism, a surgeon would expose himself to the disgrace and mortification of seeing the patient die under his hands, as happened in the example cited by Harderus. (*Apiar. Observationum, Obs. lxxxvi.*)

The possibility of tying the carotid artery, in cases of wounds and aneurisms, without any injurious effect on the functions of the brain, is now completely proved. Petit mentions, that the advocate Vieillard had an aneurism at the bifurcation of the right carotid, for the cure of which he was ordered a very spare diet, and directed to avoid all violent exercise. Three months afterwards, the tumor had evidently diminished; and, at last, it was converted into a small, hard, oblong knot, without any pulsation. The patient having died of apoplexy, seven years afterwards, the right carotid was found closed up and obliterated, from its bifurcation, as low down as the right subclavian artery. (*Acad. des Sciences de Paris, an. 1765.*) Haller dissected a woman whose left carotid was impervious. (*Opuscula Pathol. Obs. xix. tab. 1.*) An example of the total closure of both carotids, in consequence of ossification, is stated by Koberwein to be recorded by Jadelot. (*German Transl. of Mr. Hodgson's Work, p. 293.*) Hebenstreit (vol. iv. p. 266, ed. 3, of his *Translation of B. Bell's Surgery*) mentions a case in which the carotid artery was wounded in the extirpation of a scirrhus tumor. The hemorrhage would have been fatal, had not the surgeon immediately tied the trunk of the vessel. The patient lived many years afterwards. This is probably the earliest authentic instance in which a ligature was applied to the carotid artery. Mr. Abernethy's case is perhaps the second: and that in which Mr. Fleming, a naval surgeon, tied the common carotid in a sailor, who attempted suicide, and who

was saved by the operation, is still later, not having occurred till the year 1803. (See *Med. Chir. Journ. vol. iii. p. 2.*)

Dr. Baillie knew an instance, in which one carotid was entirely obstructed, and the diameter of the other considerably lessened, without any apparent ill effects on the brain. (See *Trans. for the Improvement of Med. and Chir. Knowledge, vol. i. p. 121.*) Sir Astley Cooper has also recorded an example, in which the left carotid was obstructed by the pressure of an aneurism of the aorta; and yet, during life, no paralysis, nor impairment of the intellects, had occurred. (See *Med. Chir. Trans. vol. i. p. 223.*) A similar case is related by Pelletan. (*Clin. Chir. t. i. p. 68.*)

Mr. Abernethy was under the necessity of tying the trunk of the carotid, in a case of extensive lacerated wound of the neck, where the internal carotid, and the chief branches of the external carotid were wounded. The patient at first went on well; but, in the night, he became delirious and convulsed, and died about thirty hours after the ligature was applied. This case fell under my own notice; and the inference which I drew was, that the man died more from the great quantity of blood which he lost, and the severe mischief done to the parts in the neck, than from any effect of the ligature of the artery on the brain.

In another instance, in which the common carotid was tied, on account of a wound of the external carotid by a musket-ball, complicated with fracture of the condyle and coronoid process of the lower jaw, every thing went on favourably until the seventh day after the operation. Neither the intellectual faculties, nor the functions of the organs of sense, had been at all disturbed. But, at that period, stupor, confusion of ideas, restlessness, a small unsteady pulse, discoloration of the face, and loss of strength came on, followed in the evening by a violent paroxysm of fever. On the eighth day, three copious hemorrhages took place from the whole surface of the wound, and on the ninth the man died. In this case, however, the affection of the brain and the other unfavourable symptoms would be ascribed by nobody to the effects of the ligature on the carotid, but every one would see the cause in the severe and extensive local mischief, produced partly by the musket-ball, and partly by the mode in which the operation was performed, the surgeon having extended his incisions from the parotid gland to within an inch of the clavicle! (See *Journ. Général de Méd. &c. par Sédillot.*)

That the carotid may be tied without injuring the functions of the brain, and that aneurisms of this artery admit of being cured by the operation, is now fully proved. The following is the second instance in which I have been present at the operation of tying the carotid trunk on account of a wound.

Sir Astley Cooper has the honour of having been the first surgeon who ever tied the carotid for the cure of aneurism. The operation referred to was performed November, 1805, on Mary Edwards, aged forty-four, who had an aneurism of the right carotid artery: the tumor reached from the vicinity of the chin to beyond the angle of the jaw, and downward to within two inches and a half from the clavicle. The swelling had a strong pulsatory motion. The woman also complained of a particular tenderness of the scalp, on the same side of

the head, and of such a throbbing in the brain as prevented her from sleeping.

An incision, two inches long, was made at the inner edge of the sterno-cleido-mastoideus muscle, from the lower part of the tumor to the clavicle. This wound exposed the omo-hyoideus and sterno-hyoideus muscles, which being drawn aside towards the trachea, the jugular vein presented itself to view. The motion of this vein produced the only difficulty in the operation, as, under the different states of breathing, the vessel sometimes became tense and distended under the knife, and then suddenly collapsed. Sir Astley Cooper introduced his finger into the wound, to keep the vein out of the way of the knife; and, having exposed the carotid artery by another cut, he passed two ligatures under this vessel by means of a curved aneurism-needle. The ligatures were then tied about half an inch asunder; but the intervening portion of the artery was left undivided. The pulsation of the swelling ceased immediately the vessel was tied; and on the day after the operation the throbbing in the brain had subsided, while no diminution of nervous energy in any part of the body could be observed.

The patient was occasionally afflicted with bad fits of coughing, but upon the whole went on at first pretty well. On the eighth day, however, a paralysis of the left leg and arm was noticed, attended with a great deal of constitutional irritation. November 8th, the patient could move her arm rather better; but became unable to swallow solids. November 12th, the palsy of her arm had now almost disappeared. The ligatures came away. November 14th, she was in every respect better; she swallowed with less difficulty; and the tumor was smaller, and quite free from pain. On the 17th, she became very ill; the tumor increased in size, and was sore when pressed. The wound was as large as immediately after the operation, and discharged a sanious serum. Great difficulty of swallowing, and a most distressing cough, were also experienced. The pulse was ninety-six, and the left arm again very weak. On the 21st, the patient died, the difficulty of swallowing having previously become still greater, attended with a further increase of the tumor, the skin over which had acquired a brownish red colour.

On opening the swelling after death, the aneurismal sac was found inflamed, and the clot of blood in it was surrounded with a considerable quantity of pus. The inflammation extended on the outside of the sac, along the par vagum, nearly to the basis of the skull. The glottis was almost closed, the lining of the trachea was inflamed and covered with coagulating lymph. The pharynx was so compressed by the tumor, which had been suddenly enlarged by the inflammation, that a bougie of the size of a goose-quill could hardly be introduced into the œsophagus. Sir Astley Cooper concludes with expressing his opinion that *these causes of failure may, in future, be avoided by operating before the tumor is of such size as to make pressure on important parts; or, if the swelling should be large, by opening it, and letting out its contents, as soon as inflammation comes on.* (See *Med. Chir. Trans.* vol. i.)

In one case, under the care of Mr. Coates, of Salisbury, the making of an opening, about a month after the operation, gave relief by dis-

charging seven ounces of fetid blood and pus; but three weeks afterwards hemorrhage came on from the sac, and the patient was carried off by repeated loss of blood. On dissection, an artery, capable of admitting a probe, was found to pass into the cavity of the sac. (See *Med. Chir. Trans.* vol. xi. p. 2.)

In June, 1808, Sir Astley Cooper operated, in Guy's Hospital, on a man, aged fifty, who had a carotid aneurism, attended with pain on one side of the head, throbbing in the brain, hoarseness, cough, slight difficulty of breathing, nausea, giddiness, &c. The patient got quite well, and resumed his occupation as a porter. There was afterwards no perceptible pulsation in the facial and temporal arteries of the aneurismal side of the face. On the opposite side, the temporal artery became unusually large. The tumor was at last quite absorbed, though a pulsation existed in it till the beginning of September. The man's intellects remained perfect; his nervous system was unaffected; and the severe pain, which, before the operation, used to affect the aneurismal side of the head, never returned. The swelling, at the time of the operation, was about as large as a pullet's egg, and situated on the left side about the acute angle made by the bifurcation of the common carotid, just under the angle of the jaw.

Sir Astley Cooper began the incision opposite the middle of the thyroid cartilage, at the base of the tumor, and extended the wound to within an inch of the clavicle, on the inner side of the sterno-cleido-mastoideus muscle. On raising the margin of this muscle, the omo-hyoideus could be distinctly seen crossing the sheath of the vessels, and the nervus descendens noni was also brought into view. The sterno-cleido-mastoideus was now separated from the omo-hyoideus, when the jugular vein was seen. This vessel became so distended at every expiration as to cover the artery. When the vein was drawn to one side, the par vagum was manifest, lying between that vessel and the carotid artery. The nerve was easily avoided. A double ligature was then conveyed under the artery with a blunt iron probe. The lower ligature was immediately tied, and the upper one was also drawn tight, as soon as about an inch of the artery had been separated from the surrounding parts above the first ligature, so as to allow the second to be tied at this height. A needle and thread were passed through the vessel below one ligature, and above the other. The artery was then divided. In a little more than nine weeks, the wound was quite healed, and the patient entirely recovered. (See *Med. Chir. Trans.* vol. i.)

Another successful instance, in which the carotid was tied for the cure of an aneurism, is related in a work, to which I always have the greatest pleasure in referring. (See *Hodgson's Treatise on the Diseases of Arteries*, p. 329.)

Mr. Travers tied the carotid artery in a woman, who had an aneurism by anastomosis in the left orbit. The disease had pushed the eye out of its socket. Two small ligatures were applied, which came away on the twenty-first and twenty-second days. No hemorrhage, nor impairment of the function of the brain took place, and the disease in the orbit was effectually cured. (See *Med. Chir. Trans.* vol. ii.) Another highly interesting example, in which an aneurism by anastomosis in the orbit was effectually cured by tying the carotid

artery, is recorded by Mr. Dalrymple, surgeon at Norwich. This gentleman performed the operation on the 12th of November, 1812. The patient was a female, aged forty-four. The protrusion of the eye was relieved in proportion as the swelling diminished. The violent headaches also subsided; but the eyesight was irrecoverably lost. (See *Med. Chir. Trans.* vol. vi. p. 111.)

The carotid artery has sometimes been tied with the view of enabling the surgeon to cut away swellings from the neck and side of the face, where, from particular circumstances in the cases, there was reason to fear a fatal hemorrhage without that preliminary measure. (See *Goodlad's and Arenal's Cases, in Med. and Chir. Trans.* vols. vii. and xii.)

An interesting case, in which my friend Mr. Vincent tied the carotid trunk for an aneurism, is published in the 10th volume of the latter work. (P. 212, &c.) In this example the internal jugular vein did not appear to be at all in the way during the operation; some of the fibres of the omohyoideus, however, could not be conveniently drawn aside, and were therefore divided. A single ligature was applied; the pulsation in the tumor did not entirely cease at first, when the artery was tied, but it did so two days afterwards; and the swelling was rapidly diminishing. The ligature came away about three weeks after the operation, and there was every hope of a cure; but, between the fourth and fifth week, a considerable swelling occurred between the wound and the jaw, impeding deglutition, but not the breathing. This state was followed by febrile symptoms, increased difficulty of swallowing, an attack of coughing, and impeded respiration. In the hope of affording relief, an incision was made in the tumor, from which a small quantity of pus and coagulum issued; but it was in vain, for the patient was dying. On dissection the carotid artery was found perfectly closed as far as the division of the arteria innominata. But, above the ligature, the vessel was open and inflamed, and pus was found in it. The most remarkable circumstance noticed was globules of air, adhering to the inner surface of the aorta and other large arteries, and found also under the tunica arachnoidea. The bulk of the swelling in the neck depended upon effusion of serum in the cellular membrane.

The cure of carotid aneurisms by the operation has now been so often exemplified, that even to refer to every case upon record would demand more space than I can afford. A successful instance is reported by Macaulay (*Edin. Med. Surg. Journ.* April, 1814); another by Dr. Post, who used two ligatures, and divided the artery in the space between them (*New England Journ. of Medicine and Surgery*, vol. iii. p. 205, Boston, 1814); another by Mr. Giles Lyford, proving the sufficiency of a single ligature (*Med. Chir. Trans.* vol. xi. p. 97, &c.) The case in which Mr. Goodlad tied the carotid, in order to prevent hemorrhage in the removal of a tumor involving the parotid gland, is contained in vol. vii. p. 112, &c. of the latter book. The example, in which the carotid was tied by Dr. Frick, in the hospital at Hamburgh, for the cure of a diseased parotid, is reported in the *Lancet*, No. 182. Some diminution of the swelling, and increased power of swallowing, followed; but suppuration took place, and the case ended fatally.

For the particulars of a carotid aneurism cured

by the ligature of the artery by M. Dumont, see *Diss. sur l'Aneurisme de l'Artère Carotide, par P. J. Vanderhagen*, Paris, 1815. Walther, of Landshut, in the year 1814, tied the carotid artery for the cure of an aneurism with complete success: he applied only a single ligature. (*Breschet, Fr. Transl. of Mr. Hodgson's Work*, t. ii. p. 83.) In this translation are reported several instances, in which Dupuytren and other continental surgeons applied a ligature to the carotid. Dr. Holscher, of Hanover, has also operated with success. (See *Lond. Med. Repository*, vol. xvi. No. 94.)

Of the plan of tying the carotid above the aneurism, when it is situated so low that the ligature cannot be applied below it, I have also spoken. The facts, by which the propriety of this practice has now been completely established, have also been noticed: they appear to me to reflect considerable credit on Mr. Wardrop, by whom this method of operating has been revived and extended. The practice of tying the carotid for the cure of aneurism of the arteria innominata will be noticed in the ensuing section.

On the subject of tying both carotids, I find some interesting observations made by my friend Mr. Crosse:—"Although (says he) some animals will bear a ligature to both carotids simultaneously, the human frame cannot sustain so great and so sudden an interruption to the supply of blood to the sensorium. Professor Mott has tested this question; and a case came under my own observation very recently, showing the fatal tendency of a ligature, if applied almost simultaneously to each of these arteries. An approximation has, however, been made towards ascertaining the shortest interval at which the second carotid may be tied after a ligature to the first; and it has been safely done at an interval of thirty-eight, seventeen, and even twelve days. Amongst the most striking of these cases, is that related by Professor Kuhl of Leipzig, who, on account of a pulsating aneurismal tumor of the scalp, arising from a wound of the occiput, and extending over nearly the entire surface of the head, attended by frequent hemorrhages, first placed a ligature on the left common carotid. This proceeding only partially subduing the disease, and frequent hemorrhages from the affected portion of the scalp still occurring, and threatening life, a ligature was put upon the right common carotid after twenty-seven days. This was followed by convulsions; but, after a train of very troublesome symptoms, the patient recovered, and was cured of his disease. It is worthy to be noticed, that in this, and also in other like cases, some days after both carotids had been tied, heaviness and throbbing in the head have occurred, requiring free venesection. (*J. Green Crosse, in Provincial Med. Chir. Trans.* vol. v.)

[Norris has collected the details of 149 cases in which the common carotid had been ligatured. Of these, thirty were for wound of the vessel; thirty-eight for aneurism; and the remainder for various morbid conditions about the head and neck. Of the whole number, thirty-two proved fatal, and of these, eighteen deaths occurred from cerebral disease.]

The cerebral symptoms evinced by the ligature of the carotid artery are, doubtless, due to the disturbance of the circulation through the brain that results from the diminution of the supply of blood

to that organ. They consist generally of twitchings, convulsions, and hemiplegia; and in other cases of drowsiness, stupor, coma, and apoplexy.

After deligation of the carotid, the lungs, also, are apt to suffer from congestion, as has been pointed out by Jobert and Miller, in some instances at least, apparently secondary to, and probably dependent on, the cerebral disturbance.]

DISTAL OPERATION FOR ANEURISM OF THE ARTERIA INNOMINATA.

It having been established, that aneurisms may be cured by simply lessening the impetus of the blood flowing through them, and that, although a circulation may yet continue in them for some time, the layers of coagulable lymph within the sac augment, and ultimately bring about a complete consolidation of the swelling, it occurred to Mr. Wardrop, that in aneurism of the arteria innominata, the progress of the disease might be arrested by tying its two great branches, the carotid and subclavian. Although a certain portion of blood would still continue to pass along the innominata to those branches of the subclavian on the cardiac side of the ligature, the ligature being necessarily placed on the subclavian artery, after it emerges from between the scaleni muscles, Mr. Wardrop conceived that such would yet be the diminution of the impetus of the blood in the sac, that the future increase of the tumor would be prevented, and even a permanent obliteration of the aneurismal cavity would be accomplished. (*On Aneurism*, p. 58.) The knowledge of this principle, indeed, he thinks, may be useful in the cure of many aneurisms which have hitherto been considered beyond the reach of art. In an aneurism of the innominata, Mr. Mackelcan found that nature had nearly completed a cure on this principle. The carotid artery was plugged up, and the large aneurismal swelling was filled with a coagulum, leaving only a comparatively small channel for the passage of the blood into the subclavian artery. (See *Appendix to Wardrop on Aneurism*.) However, Mr. Guthrie takes a different view of this case, and infers that a ligature on the carotid above the aneurism would have been of no use, so far as the obliteration of the arteries was concerned, unless it had been followed by inflammation of the sac and coagulation of its contents. (See *Guthrie, On the Dis. of Arteries*, p. 206.) He makes this inference, because though the artery was rendered impervious, by a natural process, the disease went on increasing, till it destroyed the patient. The coagulation of blood is all that the advocates of this plan have in view. Mr. Wardrop has seen instances, and several are on record, which illustrate the important pathological fact, and prove, beyond a doubt, that blood may coagulate in an aneurism so as to strengthen the parietes of the sac, and ultimately fill its cavity, without the circulation in the sac being, in the first instance, either suddenly or entirely interrupted.

It was the knowledge of this fact that led Mr. Wardrop to perform the operation which he has related. Nature, in the case alluded to, had already instituted a curative process by diminishing the circulation in the carotid artery; and when he found this alone not sufficient to stop the enlargement of the aneurism, he determined to place a ligature on the subclavian. In doing this, he conceived that he was strictly imitating the

process which nature herself had commenced. (P. 61.) The case of Mrs. Denmark, aged forty-five, in whom he tied the subclavian artery, and thus cured an aneurism of the arteria innominata, is highly interesting. The particulars may be read in his own publication, or in the *Lancet* for 1827. Suffice it here to state, that the operation had the effect of diminishing the size of the tumor, and causing it almost to disappear. The swelling afterwards enlarged, however, and the patient died. In the *post mortem* examination, the tumor was found occupying the central space between the sterno-mastoid muscles, and composed of three portions; one arising immediately above the sternum; another upwards along the trachea; and the third was the original portion of the aneurism, consolidated by the effects of the operation. The swelling, which underwent no diminution after death, felt like a firm fleshy mass. On laying it open longitudinally, it appeared nearly solid. The clavicular and tracheal portions of the sac were filled with firm coagulum, the cavity being chiefly limited to the division between the sternal and tracheal portions, and it was about the size of a walnut. The coats of the aorta were somewhat thickened; and it presented a few points of ossification. "On cutting into the innominata from the aorta, the aneurism was found to have originally extended from its origin to its bifurcation. The subclavian artery is divided at the place where the ligature had been applied; and both the cardiac and distal orifices are contracted, and the sides of the vessel coalesce, and adhere firmly together. The right carotid pervious, and quite healthy." I think with Mr. Guthrie, that the account of the dissection would have been improved by the statement, whether the branches of the subclavian, given off nearer the heart than the ligature, were pervious, or not. The following is the view taken by Mr. Guthrie of Mrs. Denmark's case: "It appears to me (he observes) that the operation gave rise to inflammation, and consequent coagulation in the sac, which led to a diminution of its size, without interfering with the channel by which the blood passed into the right carotid. The disease was, therefore, for the time, arrested; but, as the artery was unhealthy in the parts surrounding the aneurism, it again returned, and ultimately destroyed the patient. The same thing is clearly taking place in Mr. Evans's patient." (See *Guthrie, On the Dis. of the Arteries*, p. 190.) In the advertisement prefixed to this work is a similar prognostication with reference to Dr. Mott's very interesting case. In the appendix to Mr. Wardrop's publication, and in the *Lancet* for November, 1828, is a case in which Mr. Evans, of Belper, Derbyshire, treated an aneurism of the innominata and root of the carotid, by tying the latter vessel. Three months after the operation, the patient, a butcher and horse-dealer, thirty years of age, was well enough to attend regularly the markets and fairs of Derby, seven miles from his home. In the course of the case, three remarkable circumstances occurred: 1st. An obliteration of the principal arteries of the right arm. 2ndly. A profuse salivation. 3rdly. A disposition to paralysis of the right side; supposed, by Mr. Evans, to have arisen from a greater quantity of blood being sent to the left hemisphere of the brain than to the right. However, as such paralysis has not attended other operations, in which

the carotid was tied, the truth of the explanation seems doubtful. The palsy afterwards nearly subsided. This case did not terminate, however, in a cure; for he led a very irregular life, and the tumor, which had been stationary, began to increase, and another tumor made its appearance on the other side of the sternum. "If I were to hazard an opinion (says Mr. Evans), I should be disposed to affirm, that the operation succeeded in arresting the disease for a time, and that, under more favourable circumstances, that time might have been prolonged: but the patient's return to his usual irregular habits, and the fatigue and exercise his avocations necessarily led him into, excited the disease in the lower portion of the innominate, or, perhaps, in the aorta itself; for the original tumor is yet easily distinguished from the later enlargements." Of course, until the time for a *post mortem* examination arrives, this case must be attended with obscurity. The following are some of the particulars of the case, in which Dr. Mott, of New York, tied the carotid artery for an aneurism of the innominate. The patient, Moses R. Gardner, aged fifty-one, a farmer of sound constitution and good habits of life, about three years before he consulted this gentleman, while occupied in removing a building, was attacked with pain in the upper and back part of the neck. This afterwards extended to the right shoulder and arm, but, in time, partially subsided, and his voice became hoarse. About eighteen months before he consulted Mr. Mott, he discovered a small swelling at the upper part of the breast-bone, but did not at first remark any throbbing in it. Dr. Mott found, above the sternum, a pulsating tumor, about the size of a pigeon's egg, spreading some distance under the clavicular and sternal portions of the right sternomastoides, in the course of the subclavian artery, and extending as low down as the second rib, compressing the bronchial tubes, and producing, on the least coughing or exercise, a wheezing, not unlike that of asthma. The patient shrunk from the least pressure upon it, complaining of impeded respiration, followed by pain; its pulsations were synchronous with those of the heart, and decidedly aneurismal.

After fully explaining to him the nature of his disease, and its probable fatal termination should it be left to itself, Dr. Mott advised him to return to his home, to avoid all exertion, to be occasionally bled, and to confine himself principally to a vegetable diet; but, should he observe the least increase, either in the tumor or any of his symptoms, to apply again. In a few months he again came to New York. Dr. Mott now found that the tumor above the sternum had much increased, and, upon a careful application of the stethoscope, that it had evidently encroached more upon the chest. The *bruit de soufflet* could be heard; the thoracic viscera were sound, and the respiratory murmur distinct. In either speaking, walking, or coughing, respiration was very much impeded, and almost entirely suspended by the least pressure upon the tumor. The action of the right carotid was more feeble than that of the left, and no pulsation could be felt in its branches; the right subclavian, external to the scaleni muscles, was natural, while the axillary and brachial arteries could hardly be felt; and at the wrist no pulse could be distinguished; but the pulsations of the arteries of the left side were natural. The general health was good.

Dr. Mott was persuaded the aneurism was one of the arteria innominate, involving the subclavian and the root of the carotid, and he considered it a proper case for the operation proposed and successfully performed by Mr. Wardrop. From the evident interruption of the circulation in the right arm, and the apparent efforts of nature to effect a spontaneous cure, he determined to tie the carotid first, and afterwards the subclavian, should it be required.

"On the 20th Sept. the artery was taken up in the usual manner. 27th, 9 A.M. Slept well, and feels refreshed; thinks there is more room, as he expresses it, in breathing; complains of a little soreness of the tonsils; pulse 58, regular and tranquil; the skin natural; pulsation and size of the tumor evidently diminished. 9 P.M. Much more restless; pulse 68, and tense; in other respects the same as in the morning; being habituated to laudanum, was permitted to take a teaspoonful. 28th, 9 A.M. Slept well; breathes more easily; feels less of the pulsation in the tumor; pulse 63, and not so tense; skin natural, and cough less. Ordered a dose of magnesia and Epsom salts. 9 P.M. Has passed a comfortable day. His wife, who arrived from the country since the morning, expressed her surprise at the improvement in his voice and breathing, as well as at the difference in the beating. Pulse of the right radial artery very distinct, but intermitting from ten to fifteen beats; in the left arm 80, and stronger; coughs frequently, and expectorates freely; skin natural; tongue a little white; salts have not operated. Ordered the dose to be repeated; and if restless after its operation, to take his usual anodyne. 29th. Saluted Dr. Mott this morning with a full and fine voice, and said he was well enough to call on him. His cough and expectoration much less. Dr. Mott found him lying down, and breathing quietly; pulse 71, and regular. The radial artery of the right arm beating as last evening, with fewer intermissions, but of longer continuance; skin over the tumor more wrinkled; pulsation less and weaker. The ligature came away on the night of the 15th, and the tumor above the sternum, and pulsation, entirely had disappeared; the cough and breathing better; voice nearly natural; pulse 66, with now and then a very faint pulsation of the right radial artery; right hand a little swelled, and numbed. 22nd. Wound has just healed; weakness of the arm considerable; fingers very thick and clumsy; whole arm swelled, and pits upon pressure; no pulse in the right radial artery; breathing easy; cough and expectoration much less; can sleep easy in any position, *which he has not been able to do for many months.* 26th. Left town for his residence in New Jersey." This patient died seven months after the operation.

[Three distinct modifications of the distal operation have been practised for the cure of aneurism of the innominate. 1. The ligature of the subclavian only. 2. The ligature of the carotid only. 3. Of both vessels, with an interval of greater or less extent.

The ligatures of the subclavian only, in the third part of its course, for the cure of aneurisms of the innominate, has been practised in three cases only. Of these, two proved fatal, and the third was partially successful, owing, probably, to the carotid being occluded by disease.

The ligature of the carotid only has been practised in eight cases, and in one instance only does

the disease appear to have been benefited by the operation, and in that instance the good effects appear not to have been due so much to the operation itself as to the accident of the sac becoming inflamed, and suppurating, and thus undergoing a spontaneous cure.

In three instances, both the carotid and the subclavian have been tied; and, in the most favourable of these, two years elapsed between the ligatures of the carotid and that of the subclavian, the patient dying three months after the second operation. In one of the other cases, both arteries were tied simultaneously, the patient surviving six days. The last case in which distal ligature of the carotid has been practised, is one by Mr. Lane, of which the following is a short account:—

“J. F., thirty-six years of age, admitted into St. Mary's Hospital, July, 1852, for aneurism of left carotid, immediately above the sternal end of the clavicle, which first appeared six months previously. July 7th. The carotid was ligatured on the distal side of the tumor; the chief point worthy of note being the large size of the anterior jugular vein. After the operation, the pulsation in tumor increased somewhat, but no pulsations in branches of external carotid. On the 10th, tumor being much the same, ice was applied to it. On the 16th, it was rather harder. 19th, ligature came away; less impulse in tumor. On 29th, indistinct return of pulsations in left temporal. Aug. 5th, Tumor decidedly harder. 6th. Considerably less prominent; and the whole tumor felt more solid. 7th. Tumor was rapidly decreasing; pulsation merely at inner and lower side; some humid discharge took place from the wound, and in the night of the 22nd pure blood was discharged; V. S. ad $\frac{3}{4}$ xij. was prescribed. The patient now became feverish, and symptoms of broncho-pneumonia, with bloody sputa set in, from which he died on Sept. 13th. After death, the aneurism was found adhering to apex of left lung, with which it communicated by a circular ulcerated aperture; it was filled with firm layers of coagulum, except at commencement from aorta, and part adjoining left lung. The artery above tumor obliterated as high as external carotid.”]

OF ANEURISMS OF THE AORTA, AND VALSALVA'S TREATMENT.

This afflicting and fatal disease is by no means unfrequent, and the arch of the aorta is its most common situation. Dr. Hunter was of opinion, that the latter circumstance depended on the forcible manner in which the blood, propelled from the left ventricle of the heart, must be driven against the angle of the curvature of the vessel. Mr. A. Burns considered aneurism of the thoracic aorta more frequent, perhaps, than that of any other vessel in the body. “I have had (says he) an opportunity of examining fourteen who had died of this disease, but have not seen more than three instances of external aneurism.” (*On Diseases of the Heart, &c.* p. 215.) These proportions, however, would not correspond to common observation, external aneurisms, taken collectively, being supposed to be about as numerous as those of the aorta alone, a calculation long ago made by Dr. A. Monro, primus.

It was the opinion of Dr. W. Hunter, that the aneurismal sac was composed of the dilated coats of the artery, which parts nature thickened and

studded with ossifications, after the origin of the disease, for the purpose of resisting its increase. Mr. Hodgson also declares his decided belief, and adduces facts to prove, that many aneurisms of the aorta are formed by dilatation. Yet the celebrated Scarpa believed that the generality of aneurisms of the aorta were the consequence of a rupture of the proper coats of this large vessel; and that its cellular sheath was distended into the aneurismal sac. While Dr. W. Hunter considered the ossifications of the sac as consequences of the disease, Haller looked upon the scales of calcareous matter in the aorta as the very cause of the affection, by rendering the artery inelastic, and incapable of yielding to each pulsation of the heart. On this point Haller was right.

Aneurisms of the aorta are most common in persons who are advanced in life; and the aorta of every old subject, whether affected with aneurism or not, is very commonly marked in some place or another with ossifications, or rather with calcareous concretions. Such productions occasion a decay, or absorption, of the muscular and inner coats of the vessel, so that at length the force of the blood makes the artery give way; and this fluid, collecting on the outside of the laceration, or rupture, gradually distends the external sheath of the artery into the aneurismal sac.

“If any person, who is not prejudiced in favour of the common doctrine with regard to the nature and proximate cause of this disease (says Scarpa), will examine, not hastily and superficially, but with care and by dissection, the intimate structure and texture of the aneurism of the aorta, unfolding with particular attention the proper and common coats of this artery, and, in succession, those which constitute the aneurismal sac, in order to ascertain distinctly the texture and limits of both, he will clearly see that the aorta, properly speaking, contributes nothing to the formation of the aneurismal sac, and that, consequently, the sac is merely the cellular membrane which in the sound state covered the artery, or that soft cellular sheath which the artery received in common with the neighbouring parts. This cellular substance, being raised and compressed by the blood effused from the corroded or lacerated artery, assumes the form of a circumscribed tumor, covered externally, in common with the artery, by a smooth membrane such as the pleura in the thorax, and the peritoneum in the abdomen.” Scarpa then comments upon the differences of the mere dilatation of an artery from aneurism, a subject which has been already fully considered in the foregoing pages. (*Scarpa, On the Anatomy, Pathology, and Surgical Treatment of Aneurism, transl. by Wishart, p. 55, 56.*)

As I have already explained in the preceding columns, the views taken of this part of the subject by Scarpa are not entertained by the generality of surgeons; or rather, his doctrine is not carried by others to the extent which he has insisted upon, and it would be useless repetition to bring again before the reader the facts proving that his statements are liable to many exceptions. A case, however, recited by M. Roux, which I have met with since the foregoing pages were printed, merits notice; it was an instance in which a popliteal aneurism, unattended with pulsation, had been mistaken for an abscess and punctured, whereby the patient lost his life. On dissecting the limb, M. Roux says, “the three coats of the artery

participated in the dilatation, and the case was one of the clearest specimens which I have ever seen of a true aneurism." (*Nouveaux Elémens de Méd. Opératoire*, t. i. p. 517.)

The best pathologists now admit six varieties of aneurismal disease of the aorta. 1. *A Dilatation*, involving the whole circumference of the artery. 2. *True aneurism*, or a sacculated dilatation of only a portion of its circumference. 3. *False aneurism*, formed by ulceration or rupture of the internal and middle coats, and a dilatation of the external one into a sac. 4. *Mixed or sacculated aneurism*, where, after partial or general dilatation of all the three coats, the internal and middle burst, and the external alone expands into another sac, engrafted as it were upon the original dilatation, or true aneurism. 5. The case in which the inner coat protrudes through the outer ones. (*Dubois; Dupuytren; Laennec, De l'Auscult.* t. ii. p. 693.) A fine specimen of this is contained in Mr. Liston's collection. 6. A few very rare examples have been noticed in which, after the rupture of the internal and middle coats of the aorta, the blood, instead of distending the external coat into a swelling, insinuates itself more or less extensively between this coat and the middle one. Thus Laennec saw a case in which the internal and middle coats had a narrow fissure in them extending across two thirds of the circumference of the artery; and the blood had interposed itself between the external and middle coats, over more than half of the circumference of the aorta, from its arch to its bifurcation. (*Laennec, De l'Auscult.* t. ii. p. 700.) Two similar cases are reported by Mr. Guthrie. (*On Dis. of Arteries*, p. 40 and 43.) The late Mr. Shekelton met with a still more curious form of aortic aneurism, where the blood, after making its way through the internal and middle coats, had separated the external from the middle to the extent of four inches, and then passed again through the middle and internal coats into the canal of the artery; thus forming a new channel, and the old one being obliterated. (*Shekelton, in Dubl. Hosp. Rep.* vol. iii.)

As Dr. Hope observes (*Cyclop. of Pract. Med.* art. *Aorta*), the foregoing are the only instances on record where a fissure of the internal and middle coats has been followed by more than a circumscribed effusion of blood around it, occasioning a slight swelling of the external coat. Nichols found this in the body of George II. (*Phil. Trans.* vol. lii. p. 269); and Hodgson once met with it. (*On Dis. of Arteries*, p. 63.)

Aneurisms, and the diseases of the coats of the arteries which precede their formation, are well known to be far more common in men than in women. (*Sir A. Cooper, Hodgson, Lisfranc, &c.*) Yet women are perhaps quite as frequently afflicted with aortic aneurisms as men, though, with respect to external aneurisms, they may only exhibit the proportion of one case to fifteen or twelve in male subjects. (See *Hope, in Cyclop. of Pract. Med.* art. *Aorta*.) With respect to dilatation affecting the whole circumference, I may observe, that the great arterial trunks given off at right angles from the aorta, as the innominate and coeliac axis, generally participate in it; but, as Laennec observes, the left subclavian commonly remains unaffected, on account of the acute angle at which it leaves the arch of the aorta.

As for *true aneurisms*, almost all those of the ascending aorta and arch are originally of this

description; but the false is sometimes engrafted upon them. The tumor, which mostly inclines to the right side of the chest, generally springs from the anterior or the lateral part of the vessel, while the posterior is little, if at all, implicated. When it springs from the root of the aorta, and the middle and internal coats give way, the consequence is not a false aneurism surmounting the true, as in other parts, but a fatal extravasation into the pericardium. The reason of this is, that the portion of the aorta referred to is destitute of the cellular coat, and the pericardium, which supplies its place, not being equally extensible, bursts while the aneurism is but of small size. (See *Scarpa, On Aneurism, by Wishart*, p. 80; *Hope, in Cyclop. of Pract. Med.* art. *Aorta*; *Bertin, Bouilland, &c.*) It does not appear certain to me, that the preparation, No. 367, in the Hunterian collection at the College of Surgeons, proves, as Mr. Guthrie believes it does (*On Dis. of Arteries*, p. 70), that this doctrine is incorrect, because, though it is true that the aneurism, in this instance, is of unusual size, the inner membrane can be distinctly seen passing over the atheromatous patches. As Dr. Hope remarks, the preparation is then not one of false *aneurism*, as the middle coat is perfect, the internal one alone being removed or diseased (it is doubtful which), at the base of the sac. Scarpa only maintains, that the pericardium becomes incapable of resisting a false extravasation after the inner coats have given way.

In the Museum of the University College, the preparation No. 616 exhibits three diminutive aneurismal sacs just above the valves of the aorta, one of which has burst into the pericardium. The preparation No. 617, in the same collection, is the heart of a patient who died of the rupture of a small aneurism within the pericardium. He had been operated upon for a popliteal aneurism only three months previously. The little tumor burst just above the pulmonary artery, and a bristle is passed through the opening from the inside of the aorta, where the sac is seen directly above the valves. We know that in one case, when Sir Astley Cooper had just commenced the operation for popliteal aneurism, the patient suddenly expired, owing to a small aneurism near the root of the aorta happening to burst into the pericardium at this moment of agitation and suffering.

In thin subjects, the throbbing of the abdominal aorta is sometimes unusually plain through the integuments and viscera, and this has occasionally given rise to the suspicion of an aneurism; a circumstance which deserves to be remembered by every surgeon desirous of not pronouncing a wrong opinion. The preternatural pulsations, however, which are liable to be mistaken for those of aortic aneurisms, are of various kinds, and form a subject to which the attention of Dr. Albers, of Bremen, the late Mr. A. Burns, and others, has been very usefully directed. (See *ABDOMEN*.)

While thoracic aneurisms of the aorta are not accompanied by external swelling, the symptoms are all equivocal, as very similar ones may depend on a disease of the heart, angina pectoris, phthisis pulmonalis, &c. However, some difference depends upon the volume, position, and nature of the aneurism. Simple dilatation, when in a moderate degree, hardly produces any effect, but the most inconsiderable false aneurisms may give rise to very serious disorder. The first and most com-

mon of these effects is, the compression of the heart and lungs. (See *Laennec, On Diseases of the Chest*, by Forbes, p. 676, ed. 2.) Amongst its worst effects are those which it produces on the trachea and bronchi; for though the pressure be slight, it often suffices, in consequence of the great irritability of these parts, to produce considerable dyspnœa. It must not be imagined, however, that dilatation is an unimportant affection; for, when complicated with hypertrophy of the heart, it is one of the most formidable diseases of the organs of the circulation. (See *Hope, in Cyclop. of Pract. Med. art. Aorta.*)

The only unequivocal general sign of an aneurism of the thoracic aorta, is a tumor presenting itself externally, and attended with an expansive heaving pulsation synchronous with the action of the heart. Many of the other general signs are acknowledged to be like those of organic disease of the heart; viz. palpitation, dyspnœa, cough, tendency to syncope, terrific dreams, starting from sleep, hæmoptysis, livid complexion, cerebral or hepatic congestions, serous infiltration, &c. The identity of the general signs arises, as Dr. Hope explains, from an identity of cause; namely, an obstacle to the circulation, which depends either upon the aneurism alone, or conjointly upon it and a disease of the heart, to which sooner or later the aneurism almost invariably gives birth. When, however, the general signs coincide with those learned by auscultation, they lose their ambiguity. (See *Hope, in Cyclop. of Pract. Med. art. Aorta.*)

In aneurism of the aorta forming a defined tumor, violent and irregular throbbings frequently occur between the fourth and fifth true ribs of the left side; the same irregularity of the pulse prevails as often proceeds from organic affections of the heart; sometimes a dissimilarity of the pulses in the two wrists, an effect depending upon obstruction, or obliteration of the arteria innominata or left subclavian; the respiration is exceedingly obstructed; the voice altered; and in a more advanced period of the malady, the patient is at times almost suffocated, or actually perishes from this cause. The pressure of the internal swelling on the trachea, bronchi, and lungs, is sufficient to account for this difficulty of breathing. When the trachea, or primary bronchial divisions, are compressed by an aneurismal tumor, a harsh, wheezing, or sibilous sound characterises respiration; and when the heart is simultaneously diseased, dyspnœa sometimes occurs in most severe paroxysms, threatening suffocation. (See *Hope, op. cit.*) In many instances, the irritation and compression produced by the tumor occasion atrophy of the greater part of the lungs, and abscesses and induration throughout the portion which remains. The function of deglutition suffers interruption, in consequence of the pressure made on the œsophagus, which may even be in a state of ulceration. Thus, in one example, "the cavity of the windpipe was nearly obliterated from the pressure of the aneurism; and the extremities of four of its cartilages lay in the œsophagus, having entered that canal through an ulcer in its coats." (*Trans. for the Improvement of Med. and Chir. Knowledge*, vol. iii. p. 83.) After what has been stated, it cannot be surprising, that ere the disease manifests itself externally, affection of the lungs, or strictures of the œsophagus, should often be suspected. (*Hodgson*, p. 91; *Porter, in Dubl. Journ. of Med. Science*, vol. iv. p. 207.) On the supposition of a

stricture in the œsophagus, probangs have frequently been used.

The greater weakness of one radial pulse than the other, or its total extinction, may proceed from a variety of causes, independent of aneurism of the aorta, as contraction of the origin of either of the subclavian arteries from calcareous, cartilaginous, steatomatous, or other depositions; obstructions in the course of the artery produced by tumors, wounds, or subclavian aneurism, or from an irregular subdivision of the radial or brachial artery. (See *Hope, in Cyclop. of Pract. Med. art. Aorta.*)

An aneurism of the arteria innominata, not discovered till after the patient had died of suffocation, gave rise to great difficulty of drawing air into the chest, without any other symptom calculated to throw light on the nature of the disease. The aneurismal swelling was situated behind the first bone of the sternum, and pressed upon the trachea. The front of this tube was pushed in by the tumor, so as to present a convex prominence on the inner surface, which, however, diminished its area in a very slight degree. Mr. Lawrence adduces this fact to prove that spasm of the air-cells may be the cause of great distress in breathing. "The termination of this case (says he) is the more remarkable, inasmuch as in another patient an aneurism rising out of the arch of the aorta, and pressing on the corresponding part of the trachea, so as to produce ulceration of the internal membrane, under which there was a slight appearance of coagulated blood, caused no affection of the breath at all. The person died of a different complaint, and the discovery of the aneurismal tumor, which was very small, and filled with firm laminated coagula, was quite accidental." (*Med. Chir. Trans.* vol. vi. p. 227.) Thus, we find in thoracic aneurisms, at least previously to their attainment of a certain size, that no regularity prevails even with regard to difficulty of breathing, the symptom, which, *a priori*, one might suppose would invariably be present.

One of the least equivocal signs of an aneurism of the thoracic aorta, is a pulsation felt under the sternum, or ribs, at the upper part of the chest. But a positive opinion is not to be formed from this symptom alone, which has been known to be occasioned by some other kind of tumor behind the sternum, by adhesion of the pericardium to the heart, by fluid in the cavity of this membrane, and by hypertrophy of the heart. (*Baillie's Morbid Anat.*; and *Hope, in Cyclop. of Pract. Med. art. Aorta.*) Then another symptom of aneurism of the thoracic aorta, is pulsation above the sternum or clavicles. But this may also proceed from enlarged glands in the course of the subclavian artery, and receiving its pulsation; by varix of the jugular vein at its junction with the subclavian; or by a subclavian aneurism. A gentleman, under Mr. Maul, of Southampton, lately consulted me for a considerable throbbing felt above the sternum and clavicles, and which had been suspected to denote on the left side a subclavian aneurism. The radial pulse in the left arm was rather weaker than in the right. But the carotids also pulsated with unusual force a good way up the neck; and every little exertion brought on powerful beating of the heart. In a consultation with Sir Astley Cooper, these circumstances led us to set down the case as one of dilatation of the great arteries at the source of the circulation, with an imperfect state of the

valves, and some degree of hypertrophy. A pulsation above the sternum may be occasioned by carotid aneurism, which is liable to be confounded with aneurism of the aorta, or of the subclavian artery. Dr. Hope informs us, that in April, 1826, he saw in Guy's Hospital a case which led to much deliberation respecting the propriety of taking up the carotid above a pulsation tumor, supposed to be an aneurism of that artery. The plan, however, was judiciously abandoned, for the disease proved to be a dilatation of the aorta and innominata. (See *Hope, in Cyclop. of Pract. Med. art. Aorta.*)

Few diseases, according to Laennec, are so insidious as aneurism of the thoracic aorta. He affirms, "that it cannot be known with certainty till it shows itself externally. It can hardly be suspected, even when it compresses some important organ, and greatly deranges its functions. When it produces neither of these effects, the first indication of its existence is often the death of the individual, as instantaneously as if by a pistol-bullet." One case, recorded by Mr. Pattison, confirms the same fact, for the patient had only symptoms leading to a suspicion of rheumatism in the neck, and died suddenly of apoplexy. (*Burns, On the Head and Neck, ed. by Pattison.*) Laennec has known persons cut off in this manner, who were believed to be in the most perfect health. He admits, that percussion will sometimes enable us to detect a tumor of large size, existing within the mediastinum, or even in the back; but not to discriminate the nature of the swelling. His experience had not been sufficient to let him pronounce how far the difficulty of diagnosis was likely to be removed by the stethoscope. Dr. Hope has met with six or seven instances in which large aneurisms had existed without awakening even a suspicion of them. One, in particular, eluded the penetration of a distinguished foreign auscultator, though he explored the lungs with eminent success. (*Hope, in Cyclop. of Pract. Med. art. Aorta.*) Aneurisms of the abdominal aorta, Laennec admits, may be recognised with the utmost facility by means of the stethoscope. In this case we are sensible of tremendous pulsations, which painfully affect the ear, and the intensity of which is not at all recognised by the hand, even when sufficiently perceptible to the touch. As high up as the celiac artery, the contractions of the auricles are not in the least distinguishable. The sound of the pulsations is clear and loud. (*Laennec, On Diseases of the Chest, p. 678, &c.*)

Laennec believed that thoracic aneurism might sometimes be recognised by its *simple* or rather *single* pulsation, which is much stronger than the double pulsation of the heart; but that, in most instances, this criterion would fail, in consequence of the sound of the heart and that of the aneurism being confounded together. But as the auricular sound is not audible over the abdomen, Laennec had no difficulty in recognising ventral aneurism by the *simple* pulsation. The following are some of the criteria, specified by Dr. Hope, for distinguishing the pulsation of thoracic aneurisms from the beating of the heart; and, in some important points, his observations have received confirmation from the experience of Dr. Greene. (See *Researches on the Symptoms, &c. of Aneurisms of the Thoracic Aorta, Dubl. Journ. of Medicine, vol. vii. p. 231.*)

1. The first aneurismal sound, coinciding with the

pulse, is invariably louder than the healthy ventricular sound, and generally than the most considerable bellows-murmurs of the ventricles. 2. On exploring the aneurismal sound from its source towards the region of the heart it is found to decrease progressively, until it either becomes totally inaudible, or is lost in the predominance of the ventricular sound. If the sound emanated from the heart alone, instead of decreasing, it would increase on approximating the præcordial region. 3. The second sound actually does sustain this progressive augmentation on advancing towards the heart. 4. The aneurismal pulsation is a deep hoarse tone, of short duration, with an abrupt commencement and termination. It is compared to that of the rasping of a sounding-board heard from a distance. But the sound occasioned by valvular disease of the heart has more analogy to the bellows-murmur, being somewhat soft and prolonged, with a gradual swell and fall. 5. In simple dilatation of the thoracic aorta, the *frémissement cataire*, or purring tremor, is more considerable than in sacculated aneurism, particularly if the former be accompanied with much asperity of the internal membrane. It is also very correctly noticed by Dr. Hope, that the sound of aneurisms is, in most instances, audible on the back; and when the tumor occupies the descending aorta, it is often louder behind than on the breast; and if it is of the abrupt rasping kind, it amounts almost to positive evidence. Pulsation, he observes, attends every species of enlargement of the aorta. In dilatation, it exists only above the sternal ends of the clavicles, and always on both sides of the neck simultaneously; though, when the enlargement is confined to the ascending aorta, it is stronger on the right than on the left side. When dilatation is in the form of a pouch, and of great magnitude, it may occasion pulsation under the sternum. Carotid and subclavian aneurisms produce impulse, sound, and tremor, on the affected side only; and by this circumstance they may easily be discriminated from aortic enlargements. In sacculated aneurisms in the upper part of the chest, pulsation exists both above and below the clavicles; but Dr. Hope has generally found it stronger below. (*Hope, in Cyclop. of Pract. Med. art. Aorta.*) M. Bertin also believed, as Dr. Hope does, that Laennec underrated the power of the stethoscope to detect aneurism of the thoracic aorta. (*Mal. du Cœur, p. 143.*) Still, it is a fact, that, even with the assistance of this instrument, thoracic aneurism sometimes cannot be detected, and produces symptoms leading to a suspicion of other affections, to which the treatment is directed accordingly. (See *Porter, in Dubl. Journ. vol. iv. p. 206, &c.*)

I have mentioned, that the symptoms of thoracic aneurisms, previously to the formation of any outward swelling, often resemble those of phthisis, and the latter is sometimes actually supposed to be the disease under which the patient is labouring. But there is one distinction between the cases, pointed out by Mr. Hodgson, which may be of use, in combination with other circumstances, in facilitating the diagnosis: "In phthisis, the expectoration is either puriform, or thick and clotted; but in aneurisms which are not accompanied with disease in the lungs, as far as I have observed, it always consists of a thin frothy mucus." (*On Dis. of Arteries, &c. p. 93.*) According to Kreysig's

experience, the cough comes on at irregular periods, is violent, and attended with great efforts, the expectorated matter being forced up with vehemence. He agrees with Mr. Hodgson respecting the general quality of what is expectorated, where thoracic aneurisms are not complicated with diseased lungs; but he says that the matter coughed up also frequently consists of masses of lymph, blended with brick-red particles of blood, which masses, when thrown into water, seem as if they were composed of a ball of stringy substances. (*Germ. transl. of the latter work*, p. 137.)

From a review of many cases of aortic aneurisms, Mr. A. Burns was inclined to think, that when the ascending aorta is aneurismal, the breathing is more affected than when the arch of the vessel is enlarged; but that, in the latter case, the impediment to deglutition is greatest. (*On Dis. of the Heart, &c.* p. 244.)

False aneurisms are most common in the descending aorta, and true ones in the ascending portion of the vessel and its arch. Laennec never met with any species of false aneurism in the latter situation, but such as is consequent to the true, or simple dilatation of the artery. (*On the Dis. of the Chest*, p. 676, ed. by Forbes.)

[The symptoms of intra-thoracic aneurisms are of two kinds, *auscultatory* and *rational*.

The *auscultatory signs* vary greatly in distinctness, and even in presence. In some cases, more especially in fusiform aneurisms, they are almost from the first of a very marked and obvious character; in others, especially in sacculated aneurisms, they are absent throughout, the aneurism terminating fatally without its existence having been determined by the stethoscope. They consist of murmurs of various kinds and degrees of intensity, bellows, rasping, or whizzing; by the second sound of the heart being audible over a greater space than normal, and by the existence of dullness on percussion. These various signs may often be heard more distinctly upon, or to the left side of, the spine than at the anterior part of the chest; when occurring anteriorly they are chiefly met with on the right side.

The value of the auscultatory signs in the diagnosis of aneurisms within the chest, is not perhaps so great as in many other thoracic diseases in the early stages of the affection, and in those cases in which the aneurism continues small and sacculated throughout, or is so deeply seated as not to approach the parietes of the chest. This need not be a matter of surprise, when we reflect on the depth at which the ascending portion of the aorta and the arch are situated, how it is covered in front by the lungs and loose cellular tissue, through which sound is with difficulty transmitted; and how it is covered in behind by the spine and its muscles. When, in addition to this, it is borne in mind that aneurisms of the arch often prove fatal by bursting into contiguous cavities and canals before they have attained a greater size than a walnut or a pigeon's egg, and thus are incapable of furnishing a murmur of any very marked kind, it can easily be understood that the value of auscultation is but small in many cases of thoracic aneurisms.

The *rational signs* of intra-thoracic aneurism are of three kinds:—1. Pressure effects. 2. Pulsation. 3. Tremor.

Pressure effects may be exercised on any of the

contiguous structures, and a glance at the anatomical relations of the thoracic aorta, more particularly the arch, will enable the surgeon to judge of their complexity and importance. They will necessarily vary according to the size of the aneurism, and the portion of the aorta that is affected by it, more by the latter than the former condition. When the aneurism arises from the root of the aorta, and more especially when it is intra-pericardial, it is usually of small size, and its pressure effects will be little obvious. When the aneurism arises from the termination of the arch, or the descending aorta, it may often attain a considerable amount of development without any very obvious pressure effects being induced. Aneurisms that are situated within the concavity of the arch must necessarily give rise to pressure effects, by the compression they must exercise upon some one or other of the very important structures that are spanned by, and included within, the aortic arch. Where the anterior part of the aorta is affected, the aneurism may attain a very considerable bulk, even coming forward so as to project and pulsate between the intercostal spaces, without any very noticeable pressure effects being induced. But when the posterior wall of the artery is the seat of the disease, then severe symptoms are early set up by the structures lying contiguous to the artery and along the spine being compressed. When the upper part of the aortic arch is the seat of aneurism, a peculiar train of cerebral symptoms, such as vertigo, insensibility, or defective vision, may be induced by its interference with the circulation through the carotids.

The pressure effects that need chiefly engage our attention are: 1. Pain; 2. Dyspnoea; 3. Dysphagia; and 4. Œdema.

1. *Pain* is usually one of the earliest symptoms of intra-thoracic aneurism, and is often of great value in a diagnostic point of view, as it is often more marked when the other symptoms are the least developed. It is generally more severe in sacculated than in fusiform aneurisms, and when the posterior rather than the anterior aspect of the vessel is the seat of disease. The pain, as has been pointed out by Dr. Law, is of two distinct kinds. The first form is lancinating, intermitting, and neuralgic in its character, evidently dependent upon pressure on the spinal or sympathetic nerves. These pains are chiefly seated on the left side, shoot up the side of the head and face, down the upper arm to the elbow, along the intercosto-humeral nerve, through the chest or between the scapulæ. The second form of pain usually occurs at a later stage of the disease, is continuous, and of a boring, hot, or burning character. It seems to depend upon the perforation of the tissues, more especially the bones, by the aneurismal tumor, and chiefly occurs on the right side of the chest.

2. *Dyspnoea* is of very frequent occurrence in intra-thoracic aneurisms; in all probability it is more uniformly met with than any other single symptom. It may arise from five distinct conditions, and its characters vary with its cause.

a. From direct pressure on the trachea. In these cases the dyspnoea is attended by much and constant wheezing cough, often by whistling sounds in the chest, and by slow expansion of that cavity. There is expectoration usually of thick, tenacious, or ropy mucus.

β. From direct pressure on the bronchus. In these cases there is wheezing cough, and some degree of expectoration, with probably diminished respiratory murmur in the side affected, and puerile respiration in the opposite lung, as has been pointed out by Dr. Stokes.

γ. From pressure upon the lung. In these cases the respiration is comparatively little interfered with, the spongy tissue of the lung accommodating itself and yielding to the pressure of the tumor. After a time the pulmonic tissue will become incorporated with the wall of the sac, and then more serious difficulty of breathing, with hæmoptysis, will supervene.

δ. Dyspnœa may be, and very commonly is, induced by the irritation, compression, flattening out, or stretching of the left vagus and recurrent laryngeal nerves, by the pressure of the tumor. In these cases the larynx becomes the seat of the difficult respiration, its muscles being thrown into a state of spasm, so as to occasion paroxysmal attacks of intense difficulty of breathing. The voice becomes hoarse, croupy, or croaking. The cough has a hard, croupy, or metallic sound, and is attended by the expectoration of a thin frothy mucus. The laryngeal spasm and stridor often does not occur in ordinary respiration, but is produced under exertion, or in making the patient respire fully and deeply. The laryngeal symptoms are sometimes so much more prominent than any of the other signs of intra-thoracic aneurism, and so closely resemble chronic, or even acute, laryngitis with supervening asphyxia, that there are not a few cases in which surgeons have performed tracheotomy, on the supposition that they had to do with cases of pure and uncomplicated laryngeal disease, and in other instances this operation has been performed with the view of prolonging life, even when the dependence of the laryngeal spasm on aneurism of the aorta has been recognised.

ε. Dyspnœa may be dependent on the compression of the pulmonary veins by the aneurismal tumor. In such cases as these there would be considerable lividity of surface, and signs of pulmonary congestion.

The dyspnœa of aneurism will often be sufficiently intense to occasion death.

It may be mistaken for ordinary asthma. But the diagnosis may usually be effected by observing that in aneurism the dyspnœa of the paroxysms often comes on in the day as well as at night; are greatly increased by change of position, placing the patient either upright or recumbent, the tumor thus shifting its point of pressure. It is not, as Dr. Bellingham has pointed out, influenced by atmospheric changes, and is generally associated with laryngeal stridor. When such symptoms as these are associated with pain and dysphagia, they point very strongly, even in the absence of all auscultatory signs, to the presence of an aneurismal tumor.

Aneurisms situated within the concavity of the aortic arch are those that, either directly by their pressure on the air tube or the pulmonary veins, or indirectly by the influence they exercise on the recurrent laryngeal nerve, are chiefly associated with dyspnœa.

3. *Dysphagia* is a symptom of sufficiently frequent occurrence in aortic aneurism, Dr. Green having determined its existence in nine out of

twelve cases. It seldom occurs, however, in the earlier stages of the disease, or when the aneurism is small, and hence is of much less diagnostic value than dyspnœa. When, however, it is associated with that symptom, the combination becomes important, as the co-existence of the two conditions clearly points to the compression of the œsophagus and the air tubes by a tumor, which other diagnostic signs may prove to be aneurismal.

It is of importance to bear in mind, that in some aneurisms, especially of the descending thoracic aorta, dysphagia may be one of the most marked signs. In such cases as these, stricture of the œsophagus has erroneously been supposed to exist, and the patient has even been treated by the introduction of bougies on this supposition; an error of practice that has terminated fatally by the perforation of the aneurismal sac, when projecting against the œsophagus, by the point of the instrument.

The difficulty of deglutition in cases of compression of the œsophagus by aortic aneurism is always invariably referred to the epi-sternal notch. The dysphagia is commonly associated with pain, or the sensation of a tight cord drawn around the body.

4. *Edema*, with more or less lividity of the upper extremities, and head and neck, occasionally, but rarely, occurs. It is generally more marked on the left side, and arises from the compression of the superior cava or the innominate veins, by aneurisms springing from the fore or upper part of the arch.

Pulsation and tumor in intra-thoracic aneurisms, so far as they are observable externally, are always absent in the earlier stages of the disease, and very frequently continue so throughout the progress of the affection. Indeed, in aneurisms springing from the intra-pericardial aorta, or the concavity of the arch, death usually takes place, either by rupture into one of the serous cavities, or the air tube, or by the exhaustion induced by dyspnœa long before the aneurism has attained a sufficient size to be cognisable externally. There are, however, three portions of the thoracic aorta which, when affected by aneurism, yield external evidence, by the existence of pulsation or tumor, of the true nature of the disease. These are—1. The anterior aspect of the ascending aorta; 2. The summit of the arch; and 3. The posterior aspect of the descending aorta.

When the aneurism is situated in the anterior aspect of the ascending aorta and commencement of the arch, pulsation may be detected by pressure between the intercostal spaces on the right side of the sternum, and a thrill, as well as distinct impulse, may often be felt over that side of the chest, before any external tumor becomes visible, thus simulating the beat of the heart in addition, and opposite to the seat of the true cardiac impulse. As the aneurism increases in magnitude, an external tumor appears by the wall of the chest becoming absorbed and perforated opposite the point of greatest impulse.

When an aneurism springs from the summit of the arch, a pulsating tumor appears at the root of the neck, behind, or even above the margin of the sternum, most commonly towards the right side; and it occasionally rises so high out of the thorax, and is so distinctly felt in the neck, as to run the risk of being confounded with aneurism of the brachio-cephalic or carotid arteries; an error that may be

avoided by the impossibility of tracing with the finger the lower boundary of the tumor, and the evidence of dullness on percussion, probably of impulse, or of auscultatory evidence of aneurism below the level of the upper margin of the sternum or clavicle.

When an aneurism springs from the posterior wall of the descending aorta, a pulsating tumor may gradually develop itself to one side of the spine, or under the scapula, commonly on the left side, which may attain an excessive development fully as large as the head.]

The way in which aneurisms of the thoracic aorta prove fatal, is subject to considerable variety. These swellings do not always destroy the patient by hemorrhage: in numerous instances, the functions of the lungs, bronchi, heart, and œsophagus are so deranged by compression, that death is induced, and not a drop of blood is found internally effused. Frequently (to use the description of Mr. John Bell) before the awful and fatal hemorrhage has had time to occur, the patient perishes of sufferings too great for nature to bear. The aneurismal tumor so fills the chest, oppresses the lungs, compresses the trachea, and curbs the course of the descending blood, that the system, with a poor circulation of ill-oxygenated blood is quite exhausted. And thus, though the patient is saved from the most terrible scene of all, he suffers great miseries; he experiences in his chest severe pains, which he compares with the stabbing of knives; terrible palpitations; an awful sense of sinking within him; a sound within his breast, as if of the rushing of waters; a continual sense of his condition; sudden startings during the night; fearful dreams and dangers of suffocation; until with sleepless nights, miserable thoughts by day, and the gradual decline of an ill-supported system, he grows weak, dropsical, and expires. (See *Anatomy of the Human Body*, by John Bell, vol. ii. edit. iii. p. 234, 235.) Cruveilhier relates the particulars of one very interesting case of aortic aneurism, where two swellings existed, one of which had pressed so strongly on the pneumo-gastric nerve, as entirely to have disorganised a portion of it. The patient suffered frequent syncope, and died from general derangement of the pulmonic and gastric functions, and not from the rupture of the aneurism, which, however, if the patient had lived a little while longer, would have burst into the trachea, the mucous membrane of which was ulcerated in more places than one. (See *Cruveilhier, Anat. Pathol.*) In this example the left subclavian vein had been rendered impervious by the pressure of the swelling.

Mr. A. Burns saw two examples, in which the patients died instantaneously, though their aneurismal tumors were very small, and had not burst. Both these patients were in the early stage of pregnancy. (*On Diseases of the Heart*, p. 236.)

The situations in which aneurisms of the curvature of the aorta burst, are different in different cases. Sometimes the swelling bursts into the cavity of the chest, or that of the pericardium, and the patient drops suddenly down. The left cavity of the pleura is by far the most frequent situation in which thoracic aneurisms of the aorta burst. (*Laennec, On Dis. of the Chest*, p. 677.) They also frequently burst into the posterior mediastinum. They rarely open into the cavity of the right pleura. When the coats of the aorta give

way within the pericardium, where they only receive a slight external membranous covering, this is apt to be also ruptured at the same time, so as to bring on copious effusion of blood, which oppresses the action of the heart, and produces immediate death. In other examples, the blood is effused into the trachea, or bronchi; and the patient, after violent coughing and ejections of blood from the mouth, expires. Sometimes, after the tumor has become closely adherent to the lungs, it bursts into the air-cells, through which the blood is widely diffused. An example of this termination of the disease was observed by Laennec; who also saw another case, in which, if the patient had lived a little longer, the same occurrence in all probability would have happened. Ehrhardt is not aware that this mode of rupture has been noticed by other writers. (*De Aneurysmate Aortæ*, p. 21, 4to. Lips. 1820.)

Amongst the most remarkable local effects of aneurisms of the aorta, are those on the vertebral column. They often destroy it to a very great depth. This is entirely the work of interstitial absorption, there never being any mark of suppuration. On the side next the vertebræ, the sac is completely destroyed, and the circulating blood is bounded by the naked bone. In certain cases, the swelling beats its way through the ribs; even the spinal marrow may be injured, and the patient suffers a species of death somewhat less violent and sudden. In one case of an enormous aneurism of the abdominal aorta, reported in No. 259 of the *Lancet*, the left leg and thigh were much wasted, and quite paralytic. This seemed to arise, however, from the pressure on the nerves of the lower extremity, and not from injury of the medulla spinalis.

The preparation No. 623 in the Museum of the University College is an aneurism of the aorta, which made its way through the ribs, destroying part of them and the lateral portion of the spine, so as to expose the medulla. The tumor presented itself below the scapula, and burst into the trachea by an ulcerated opening near its bifurcation. In the Hunterian Collection is a large aneurism of the commencement of the descending aorta, which caused the absorption of parts of several of the ribs, and of the bodies of the fourth and fifth dorsal vertebræ, the aneurism forcing its way there into the spinal canal. (See *Guthrie, On Dis. of Art.* p. 96.)

The effect of aneurism in producing absorption of the osseous texture, while the intervertebral substance remains little or not at all injured, is noticed in the previous part of this article.

But although aneurisms in the chest do sometimes protrude at the back, a circumstance that depends on the particular situation of the disease (see *Pelletan, Clinique Chir.* t. i. Obs. 7, p. 84), they more commonly rise towards the upper part of the breast, where a throbbing tumor occurs, which has caused an absorption of the opposing parts of the ribs and sternum, and sometimes dislocated the clavicle. Corvisart saw an instance in which an aneurism of the aorta had dislocated the sternal extremity of the clavicle; and Duverney makes mention of a case in which, besides the displacement and injury of the clavicle, the sternum and scapula were partially destroyed. I attended a case with Dr. Pinckard, where an aortic aneurism had produced considerable displacement of the scapula. Guattani speaks of an

example in which the clavicle was bent by a large aneurism, of which a portion as large as a pigeon's egg projected above the bone. (*Lauth*, p. 168.) And Morgagni has described a case where the upper bone of the sternum, the sternal ends of the clavicles, and the adjoining ribs were destroyed by the pressure of a large aneurism of the front of the curvature of the aorta, and the disease presented itself externally, somewhat in the form of a boil. (*Epist.* 26, art. 9.)

The swelling towards the close pulsates in an alarming way. The blood is only retained by a thin covering of livid skin, which is daily becoming thinner and thinner. At length, a point of the tumor puts on a more conical, thin, and inflamed appearance than the rest; a slough is formed, and on this becoming loose the patient is sometimes instantaneously carried off by a sudden gush of blood.

MM. Payen and Zeink met with an instance of the rupture of an aneurism of the aorta into the pulmonary artery. (*Bulletin de la Faculté de Méd.* 1819, No. 3.) And Dr. Hope informs us, that Professor Monro, tertius, showed him a preparation of an aneurismal pouch, springing from the aorta, directly against the pulmonary artery; so that, if the patient's life had been prolonged, the aneurism would probably have burst into the latter vessel. (*Hope*, in *Cyclop. of Pract. Med.* art. *Aorta*.) In the Hunterian Collection at the Royal College of Surgeons in London is a preparation, No. 366, exhibiting a sacculated aneurism of the ascending part of the aorta, and a communication formed between the nipple-like portion of the tumor and the pulmonary artery by ulceration, immediately above and between two of the sigmoid valves. (*Guthrie*, *On Dis. of Art.* p. 60.)

Some additional examples of this nature are detailed by other writers. (See *Bulletin de la Faculté de Médecine*, No. 3, in which there are two cases; *Sue*, in *Journ. de Méd. continué*, t. xxiv. p. 124; and *Bulletin de la Faculté*, &c. t. xvii. p. 16.)

Aneurisms of the arch of the aorta are stated to have adhered to, and burst into, the right auricle of the heart, and thus to have produced instant death. (See *Med. Chir. Journ.* vol. vi. p. 617; *Bulletin de la Société de Médecine à Paris*, 1810, No. 3, p. 38.)

A case in which an aortic aneurism projected into the ventricles of the heart, is described in a modern publication. (See *Dublin Journ. of Med. Science*, No. 27.)

The cases recorded, in which aneurisms of the thoracic aorta have burst into the œsophagus, are beginning to be more numerous than formerly. Bonetus and Morgagni relate no examples of it; nor are there any in the comprehensive treatises of Scarpa and Hodgson. Corvisart speaks of an instance which had been seen by Dupuytren, of which, however, no description is given. Yet the possibility of the occurrence is not a matter of speculation or doubt. A case of this description is noticed by Matani (*De Aneurism. Præcordiorum Morbis*, p. 120); another is alluded to by Ehrhardt as being related by Copeland (*Comment. de Aneurismate Aortæ*, p. 22; *Cerutti, Catal. Prop. Pathol.*); an instance is described by Bertin (see *Bulletin de la Faculté de Méd.* 1810, p. 14); and a very interesting one, attended with disease of the spinal cord and paralysis, is given by Dr. Molison. (See *Edin. Med. Chir. Trans.* vol. iii. p. 173.)

I have recorded one example myself (see *Med.*

Chir. Trans. vol. xvi.). This was remarkable for the length of time which the patient lived after the first rupture of it, and on account of the diminution of the external swelling and of the displacement of the scapula.

Sauvages is one of the writers who have adduced proofs of this mode of rupture: *Cadavere aperto, inveni ventriculum septem vel octo libris sanguinis distensum, aortam ad brachii magnitudinem per spatium septem vel octo pollicum dilatatam, et orificium denarii magnitudine aortæ et œsophago continuo commune, quod tamen quinque cristæ carneæ, veluti valvulæ, ex ambitu orificii oriundæ et circumpositæ potuerunt obturare. Per hoc orificium, sanguis ex aorta fluxerat in œsophagum.* (*Nov. Method*, t. ii. p. 298.) A similar case was published by Brichetau. (See *Bulletin de l'Athénée de Méd. de Paris*, Dec. 1816.) Laennec met with three examples of death from this cause. (*On Dis. of the Chest*, p. 677, ed. by Forbes.) The same distinguished professor met with an aneurism of the descending aorta, where the tumor had made such pressure on the thoracic duct, that this tube was partly destroyed, and all the lymphatic vessels were found uncommonly turgid. (*Journ. de Méd. par Corvisart*, t. ii. p. 15.) With the exception, perhaps, of one instance given on the authority of Lancisi (*Lauthii Collect.* p. 38), no other example of this description is upon record.

An instance is reported by Corvisart, in which the pressure of an aneurism of the ascending aorta had nearly obliterated the termination of the lower vena cava, and a fatal attack of apoplexy was the consequence. (*Mal. du Cœur*, p. 342.) Other examples of this are reported by Corvisart, Bertin, and Dr. Hope.

Aneurisms of the arch of the aorta may occasion a tumor, so much like that of a subclavian aneurism, as to be in danger of being mistaken for the latter disease. An example of this kind is related by Mr. Allan Burns: "A case," says he, "on which several of the most distinguished practitioners of Edinburgh, and almost every surgeon in Glasgow, were consulted. The nature of the disease appeared to be so decided, and its situation in the subclavian artery so clear, that, on that subject, there was no difference of opinion. Some were, however, of opinion that an operation might be performed, while others were fully convinced that the case was hopeless. For myself, I must confess that I was firmly persuaded, that, in the early stage of the disease, an operation might have been beneficial," &c. (*Surgical Anatomy of the Head and Neck*, p. 30.) After death, the vessel which was supposed to have been most materially affected, was found perfectly healthy. (P. 39.)

After detailing all the particulars of this interesting case, Mr. A. Burns observes, that "it corroborates Sir Astley Cooper's remark, that aneurism of the aorta may assume the appearance of being seated in one of the arteries of the neck; an inference drawn from the examination of a case which came under his own observation, and of which he had the goodness to transmit a short history to me, along with a sketch illustrative of the position of the tumor. In one case the aneurism was attached to the right side of the aortic arch, and involved a part of the arteria innominata; in Sir A. Cooper's, the tumor arose from the left side of the arch, from between the roots of the left subclavian and carotid arteries. It formed a

Florence flask-like cyst, the bulbous end of which projected at the root of the neck from behind the sternum, and so nearly resembled aneurism of the root of the carotid artery, that the practitioner who consulted Sir A. Cooper actually mistook the disease for carotid aneurism." (*Allan Burns*, op. cit. p. 41.)

The preceding statement has received full confirmation from the observations of an intelligent writer. "I have seen (says Mr. Hodgson) several cases of aneurism arising from the superior part of the arch of the aorta, which protruded above the sternum and clavicles; and, in one instance, the space between the tumor and the sternum was so considerable, that it was proposed to tie the carotid artery for an aneurism, which dissection proved to arise from the origin of the arteria innominata, and from the arch of the aorta." (*On the Dis. of Arteries and Veins*, p. 90.)

As I have already noticed, aneurisms of the aorta are most frequent at its curvature; but they are also met with on the other portion of this vessel in the thorax, and likewise on that part of it which is below the diaphragm. In subjects predisposed to aneurisms, such swellings are frequently seen affecting various parts of the aorta at the same time.

When the disease occurs in the abdominal aorta, a preternatural pulsation generally becomes perceptible at some particular point. The pressure of the tumor disturbs the functions of the viscera. The functional derangements, however, produced by aneurisms of the abdominal aorta, are generally much less urgent than those arising from aneurism in the thorax. The abdominal viscera bear compression without evil consequences much better than the thoracic ones; and the tumor, instead of being pent up in a rigid bony case like the chest, are not prevented from expanding freely, in almost every direction, because the intestines and the abdominal parietes readily yield in the requisite degree. As Dr. Hope observes, here the pressure of the tumor on any particular organ is in a great measure obviated by the want of counter-pressure. "Ventral aneurism, however, sometimes deranges the respiration by preventing the due descent of the diaphragm; an effect which may proceed either from the magnitude alone of the tumor, or what is much more common, from its being seated near or in the substance of the muscle, and impeding its motions. Ventral aneurism is also occasionally characterised by involuntary evacuations of the urine and feces, by remarkable alternations of constipation and diarrhoea, and by deep-seated excruciating pains, resembling those of lumbar abscess. These symptoms arise from compression of the nerves, particularly the hypogastric plexus around the aorta." (See *Hope*, in *Cyclop. of Pract. Med.* art. *Aorta*.)

In the Museum of the University College are several valuable preparations, illustrative of aneurism of the abdominal aorta. No. 619 is an aneurism of this vessel, implicating the mesenteric and renal arteries. No. 621 is an aneurism of the aorta at its bifurcation. No regular sac. Tumor extends down over the forepart of the sacrum. Vena cava obliterated at the point where it receives the two iliac veins. No. 622 is an aortic aneurism, consisting of two large sacs at the sides of the lumbar vertebræ, the texture of whose bodies is more or less destroyed, while the inter-

vertebral substance is entire. During life, the disease was not suspected. The patient suffered excruciating pain in the lower part of the belly. A few days before death a large tumor presented itself on the left side of the abdomen, with symptoms of internal hemorrhage. In the *post-mortem* examination blood was found between the abdominal muscles and the peritoneum, and the viscera were covered with coagula. The tumor had burst in two places on the right side. The shape of the kidneys was altered by the pressure of the tumor, which adhered to the spleen and pancreas. No. 625 is an aneurism of the aorta, where it passes between the crura of the diaphragm, and projects into both sides of the chest; while a portion of it, on the right side, descends into the abdomen. The bodies of the vertebræ partly absorbed. Death from effusion of blood into the chest.

VALSALVA'S TREATMENT.

Aneurisms within the thorax and abdomen, being entirely out of the reach of operative surgery, have been too commonly abandoned as unavoidably fatal, and when any thing has been done in such cases, it has generally been only with a view to palliation. Moderating the force of the circulation by bleedings and low diet, avoiding every thing that has the least tendency to heat the body, or quicken the motion of the blood, keeping the bowels well open with laxative medicines, and lessening pain with opiates, have been the means usually employed. Of late years, also, digitalis, which has a peculiar power of diminishing the action of the sanguiferous system and impetus of the blood, has been commonly prescribed. In Germany, the superacetate of lead has been used for many years for the same purpose; and Dupuytren, Laennec, and Bertin have employed it frequently with advantage in France. The dose, at first, should be half a grain, combined with the same quantity of opium, and given thrice a day. The dose is gradually increased to a grain three or four times a day. Dr. Hope informs us, that he has always found any gastric irritation from it removed by a dose or two of castor oil, promptly administered, and mucilaginous diluents. (See *Cyclop. of Pract. Med.* art. *Aorta*.)

That the diminution of the force of the circulation will prevent the increase of an aneurism, Mr. Hodgson considers illustrated by the following circumstance: If two sacs exist in the course of the same artery, the obstruction which is caused by the passage of blood into the upper, serves to remove the force of circulation from the lower, which becomes stationary, or its cavity is obliterated with coagulum. (*On Diseases of Arteries*, &c. p. 149.) Mr. Crosse refers to a recent case, in which a popliteal aneurism was cured by another aneurismal swelling taking place in the thigh. The latter was afterwards cured by an operation. (See *Prov. Med. Surg. Trans.* vol. v.)

It was the opinion of the celebrated Valsalva, that the utility of a lowering plan of treatment might do more than merely retard the death of aneurismal patients. It was his belief that the method might entirely cure such aneurisms as had not already made too much progress; and he put it into practice with such rigour and perseverance that the treatment became considered as particularly his own. The plan alluded to is not described in his writings, but was published in the

first volume of the Commentaries of the Academy of Bologna, by Albertini, one of his fellow-students; and several persons, who had learned this method of Valsalva, afterwards imparted it to others. Thus, as Morgagni was passing through Bologna, in 1728, Stancazi is said to have informed him of Valsalva's practice. (See *Kreysig, Ueber die Herzkrankheiten*, b. ii. p. 728.)

After taking away a good deal of blood by venesection, Valsalva used next to diminish the quantity of food gradually, till the patient at length was allowed only half a pint of soup in the morning and a quarter of a pint in the evening, and a very small quantity of water, medicated with mucilage of quinces or with the lapis osteocolla. When the patient had been so reduced as to be incapable of getting out of his bed, Valsalva used to give him more nourishment, till this extreme debility was removed. Valsalva was sure that some aneurisms thus treated had got well, because every symptom disappeared; and his conviction was verified by an opportunity which he had of dissecting the body of a person that had been cured of this disease, and afterwards died of another affection; for the artery which had been dilated was found contracted and in some degree callous.

Morgagni states that this method of treating aneurisms is somewhat like the plan which Bernard Gengha tried with success, as well as Lancisi; and he refers us to the 24th chapter of the 2nd vol. of the Anatomy of the one, and to lib. ii. cap. 4 of the Treatise on the Heart and Aneurisms of the other. But Sabatier tells us that, in consequence of this instruction, he examined both these works, without finding anything on the subject. However this may be, we are informed by the latter, that he noticed the good effects of the practice in an officer, who had an alarming aneurism in front of the humeral extremity of the clavicle, in consequence of a sword-wound in the axilla. The patient, after having been bled several times, was confined to his bed, and kept to an extremely low diet. He was allowed as drink only a very acid kind of lemonade. He took pills containing alum, and the swelling was covered with a bag full of powder of oak bark, which was every now and then well wet with port wine. By perseverance in this treatment, the swelling was reduced to a smallish hard tubercle, having no pulsation, and a perfect cure ensued. (See *Sabatier, Médecine Opératoire*, tom. iii. p. 170—172.)

Guerin recommended the application of ice-water, or pounded ice, to aneurismal swellings; a plan which he represents as being often of itself sufficient to effect a cure. This topical employment of cold applications may be rationally and conveniently adopted in conjunction with Valsalva's practice.

The most interesting facts in proof of the efficacy of this mode of treatment were published some years ago by Pelletan. The following extract from a well-written critique on "*Pelletan's Clinique Chirurgicale*," will serve to convey to the reader some idea of the important information contained in the memoir on internal aneurisms:—"The intent in the treatment is to reduce the patient gradually to as extreme a degree of weakness as is possible without immediately endangering life. It is done by absolute rest, a rigorous diet, and bleeding; to these means, M. Pelletan adds

the external application of ice, or cold and astringent washes, &c. He has here detailed many cases, from his own practice, of partial or complete success, which cannot be too generally known, as they may be the means of creating in some, and of confirming in others, a good opinion of the only method of treatment which has been found at all efficacious in a dreadful, and not an unfrequent, organic disease.

"Of the cases here recorded, some appear to have been cured; in others, the treatment had marked good effects. In extreme cases, at best, it afforded but partial and temporary relief. In one case, that of a robust man, an aneurism at the root of the aorta, with a pulsating tumor of the size of an egg, projecting between the ribs (the edges of which were already partly absorbed), was reduced, so as to recede within the ribs in the course of eight days. At the end of this time, the patient refused to submit any longer. The tumor did not appear again for nearly a year, although he returned to very drunken and irregular habits. He died in about two years and a half, with the tumor again appearing, and much increased in volume. The aneurismal sac communicated with the aorta, by a smooth and round opening opposite to one of the sigmoid valves. There can be no doubt of the efficacy of the treatment in this case; and it is highly probable, that his health and his life might have been long preserved but for his own indiscretion. In a case somewhat similar, but not so far advanced, the patient appears to have been cured. There was a swelling on the right side of the breast, about six inches in circumference, with a very strong beating. The pulsation was accompanied with a pain, which stretched towards the scapula and the occiput. It was evident that the disease was an aneurism of the arch of the aorta. The patient was a crier, of a strong frame, who was accustomed to drink freely. In the four first days, he was bled eight times, drawing three basins, 'palettes,' in the morning, and two in the evening. On the fifth, the pains and the beating were much lessened, but the pulse was still full. He was again bled once. The pulse was in a favourable state as to strength till the seventh day, when it again rose, and the man was twice bled.

"During this time, the man was kept to a most rigorous diet. A cold poultice of linseed and vinegar was placed on the tumor, and renewed when it became warm. At the end of eight days, the good effects of this plan were very evident; the pain and the pulsation were gone. The patient, though weak, was in health, and tranquil. He was now allowed more food by degrees. At the end of four weeks from the commencement of the treatment he left the Hôtel Dieu well. He afterwards led a sober life, and became fatter, without any vestige of disease, except a slight and deep pulsation at the part in which the aorta may always be felt beating in its natural state. He died two or three years afterwards of another complaint. His death was not known, and the body was not examined." (See *London Med. Review*, vol. v. p. 123.)

Pelletan also cured by similar treatment a large axillary aneurism, which was deemed beyond the reach of operative surgery. On the thirteenth day, the patient was reduced to a degree of weakness which alarmed many of the observers. From that time, all pulsation in the tumor ceased. The contents were gradually absorbed;

and the patient returned to his former laborious life with his arm as strong as ever. The pulse at the wrist was lost in consequence of the obliteration of the axillary artery, and the limb only receiving blood through the branches of the subclavian artery. "*Il y a beaucoup d'exemples d'aneurismes guéris spontanément et sans le secours de l'art* (says Pelletan); *mais on ne peut leur comparer le cas que nous venons de décrire: l'état extrême de la maladie, l'énergie des moyens employés, et l'effet immédiat et successif qui en est résulté, prouvent assez que le succès a été dû tout entier à l'art.*" (*Clinique Chir.* tom. i. p. 80.)

In this work we find not less than three cases in which aneurism of the aorta is stated to have been effectually cured. One instance was greatly relieved; but the disease returned the next year in consequence of the patient's intemperate mode of life. In another example, an aneurism at the origin of the aorta was cured; but the disease recurred in another part of that vessel further from the heart. Even such cases as proved incurable, to the number of fourteen, all received various degrees of palliation from the treatment adopted.

In Mr. Hodgson's work on Diseases of the Arteries, p. 146, 147, several other instances are adduced, in which the utility and efficacy of a debilitating plan of treatment are illustrated. In the same publication, as I have previously explained, are various interesting facts, which tend to prove, that when aneurism of the aorta is lessened or cured, this great vessel itself may remain pervious. The progress of the disease is stopped by the blood coagulating in the sac, and closing the communication between the cavity of the aneurism and that of the artery.

The diet should consist principally of fluids, and it should be gradually reduced. Pelletan sometimes allowed only two basins of broth in twenty-four hours, and lemonade as a common drink. Valsalva, by degrees, increased the food to half a pound of pudding in the morning, and a quarter of a pound in the evening, with a limited quantity of water. By gradual reduction, the solid food may be brought down to four ounces, and fluids to eight. Both the body and mind should be kept in the most perfect quietude; and if the plan is to be strictly enforced, the recumbent position must be constantly maintained. The frequent administration of purgatives, which weaken the action of the heart, is another part of this system of treatment.

It must be confessed, in regard to Valsalva's mode of treatment, that some experienced men do not place confidence in it. Boyer declares himself against it, as not being really efficacious; and he states, that some time ago, it was tried twice in the Hôtel Dieu of Paris. The first trial was made on a patient with an axillary aneurism, which could not be operated upon on account of its situation; the second on a woman, who had an aneurism of the abdominal aorta. In both cases the tumor was large, and its parietes reduced to the cellular coat and the surrounding cellular substance. In these two aneurisms, the progress of the swelling was rapid, and its rupture happened precisely at the moment when the treatment had been pushed to the utmost, and there ought to have been the greatest hope. (*Traité des Maladies Chir.* t. ii. p. 121.)

Sir Astley Cooper declares, that he has seen

but little benefit result from this treatment of the disease. According to his experience, only two measures are useful; viz. venesection when the pulse is hard and full; and the administration of the carbonate of soda in considerable doses, which, with entire rest, seem to prevent the increase of the swelling. But, he adds, that the soda is at length unavoidably given up, on account of its producing petechiæ. Sir Astley believes, that the irritability and quickened pulse produced by antiphlogistic treatment, often do as much injury as the natural force of the circulation. (*Lectures, &c.* vol. ii. p. 48.)

Small occasional bleedings are safer than large ones. In an aneurism of the aorta, especially when combined with organic disease of the heart, bleeding should never be carried to syncope, as, in such cases, this is apt to be alarmingly protracted, and sometimes to terminate fatally. (*Sir Astley Cooper, Dr. Hope, &c.*) The blood should, therefore, be drawn slowly, and in the recumbent posture. Nor should venesection be performed during a paroxysm of palpitation, as the exhaustion consequent on it, superadded to that occasioned by the loss of blood, might depress the patient beyond the possibility of restoration. (See *Hope, in Cyclop. of Pract. Med.* art. *Aorta*.)

M. Roux expresses his entire disbelief in the possibility of an aneurism of the aorta being ever completely cured by Valsalva's mode of treatment, because he imagines that such change could not happen without the tube of that great vessel becoming impervious, and of the lower parts of the body then perishing from stoppage of the circulation. But he bears witness to the utility of such treatment, and recites a case which he attended himself, where an aneurism made a considerable projection on the left side of the sternum, where the cartilages of the third and fourth ribs were raised, the throbbings very forcible, and the sense of suffocation such that the patient was obliged to keep himself constantly quiet; yet, says M. Roux, though the disease now exists, it forms no prominence on the chest; the pulsations can only be obscurely felt between the ribs; the respiration is but slightly oppressed; and the patient is capable of attending to his business. (*Nouveaux Elém. de Méd. Opér.* t. i. p. 510, 8vo. Paris, 1813.) If any one doubt the possibility of retarding the progress of an aortic aneurism by bleeding, I would refer him to a case which was laid by me before the profession not long ago. The aneurism burst by a small ulcerated opening into the œsophagus; and after the loss of a vast quantity of blood, not only did the hemorrhage cease for a considerable time, but the external swelling subsided, and the base of the scapula, which had been pushed forwards and backwards by it, returned into its natural position again. (See *Med. Chir. Trans.* vol. xvi. p. 320.)

[Aneurisms occur in connection with two distinct constitutional conditions that require different methods of treatment:—

1. When occurring in robust and plethoric individuals the object should be to reduce the hyperæmic condition, and thus to lessen the dilatation of and the pressure upon the arteries. This may be effected by rest in bed, the avoidance of all stimuli, and the gradual diminution in the quantity of animal food that is given, with the occasional administration of a purge, and perhaps the em-

ployment of small bleedings from time to time. The diet recommended by Dr. Bellingham, consisting of two ounces of bread and butter for breakfast; two ounces of bread and the same quantity of meat, for dinner; and two ounces of bread for supper, with a little milk and water, is perhaps the best on which patients of this class can be placed.

2. When aneurism occurs in feeble, cachectic, or anæmic individuals, the object is to improve the plasticity of the blood, at the same time that the irritability of the heart is lessened. This is usually best effected by putting them on a dry diet, by the administration of opiates, and of iron. In all cases bodily exertion and mental excitement must be carefully avoided.]

INTRACRANIAL ANEURISM.

[Aneurisms within the cranium may arise from any of the arteries that are met with in this situation, though some are much more liable than others to the occurrence of this disease. Wherever situated, however, they are of rare occurrence.

Of twenty-seven cases of this disease, I find 10 affecting the basilar artery.

5	„	anterior cerebral.
3	„	one internal carotid.
1	„	at junction of internal carotid and posterior communicating.
2	„	anterior communicating.
1	„	posterior cerebral.
2	„	both internal carotids.
1	„	posterior communicating.
1	„	artery of the corpus callosum.
1	„	branch of the meningeal artery.

The greater frequency of this disease in the basilar artery may probably be dependent on its larger size, and the consequently greater impetus of the blood to it.

Intracranial aneurisms are almost always formed by the uniform dilatation of the whole of the calibre of the artery; the false or sacculated variety being rarely if ever met with. I am not acquainted with any mention of this. The coats of the arteries in this situation being very thin and unprovided with any external cellular sheaths that would support the impetus of the blood, rupture of the vessel would rather occur than partial dilatation if one portion only of the circumference were diseased. Occasionally, though more rarely, the dilatation is fusiform; of this a preparation in University College Museum, is a good illustration. When it does occur, it is probably confined to the basilar artery.

The disease would appear to be of slow growth, and the sac becomes filled with lamellated coagula, sometimes so completely as to occlude the orifice of the artery from which it springs.

The size the disease in this situation attains before death results, is sometimes considerable; thus, in a case that occurred some years ago at the University College Hospital of aneurism of the basilar artery, the tumor was nearly as large as a walnut; in another case it somewhat exceeded this size. Mr. Smith, in the *Dublin Journ.* vol. xxv. mentions a case of multilocular aneurism of the left posterior cerebral artery as large as a small apple, and Serres one as large as a hen's egg. On the other hand, it occasionally proves fatal by rupture, before having reached beyond a very small size, not larger than a pea or nut.

It is seldom that more than one of the arteries

of the brain suffers aneurismal dilatation. In the Museum of the College of Surgeons, however, are the preparations (Nos. 1687 and 1688) of an aneurismal dilatation of both internal carotid arteries resembling "two bulbs about five-eighths of an inch in diameter, filling up the hollow on each side of the sella turcica, which were evidently dilatations of the carotid arteries, and from their being filled with laminae of coagulated blood there could be no doubt of their being aneurisms. Of these aneurisms, the one on the left side was largest. That on the right side communicated with the cavity of the artery, which was not the case with the other."

A case occurred in University College Hospital some years ago, under the care of Dr. Thomson, in which a somewhat similar condition existed. A man, forty-nine years of age, had fallen on his head some months before admission into the Hospital; since then he had been garrulous, silly, and very irritable, becoming readily intoxicated. He suddenly became insensible and convulsed, with vomiting and laborious breathing; he could close both eyes, but the right pupil was dilated; the left side was paralysed. He was treated for apoplexy, got slightly better, but died in ten days from the first attack. On examination, an aneurism a little larger than a hazel nut was found on the trunk of the right carotid, where it gives off the middle cerebral artery, and another small one on the curve of that artery. There was a globular aneurism on the same artery on the opposite side. The basilar artery was thickened, white, and opaque, as was also the other larger arteries of the brain. There was softening of both anterior cerebral lobes, especially the right one.

The arteries of the brain are very commonly healthy in these cases; out of four instances of intracranial aneurism that have fallen under my observation, the other vessels of the brain have been healthy in three cases, and atheromatous in but one. In one case I have seen aneurism within the cranium associated with aneurism elsewhere, —in the thoracic aorta.

The causes of intracranial aneurism are very obscure. It may be supposed that the comparatively small diameter of the arteries within the cranium would render them little liable to the occurrence of spontaneous aneurism, were it not that the anatomical characters and physiological, relation of these vessels predispose considerably to the occurrence of this affection, there being no other set of arteries in the body of the same size as those within the cranium, in which spontaneous aneurism so frequently occurs. This can only be accounted for by the thinness of their coats, and the want of an external cellular sheath rendering them unable to support the increased pressure from within, to which they are occasionally subjected in consequence of the alteration in the pressure of the cerebral circulation at different periods, the result of some variation in the relative quantities of the different fluids within the cranium, or of determination of blood to the brain. This would more particularly be the case if their natural elasticity had already been impaired by the occurrence of atheromatous or other degeneration of their coats. As these changes are the natural consequences of advance in age, we shall find the tendency to the occurrence of this disease increase with advancing years. Thus of nineteen cases in

which the patient's age is given, we find only one case which occurred as early as fourteen. Of the remaining eighteen cases, four only occurred in persons under fifty; of the remaining fourteen, ten were met with between fifty and sixty, and four in the next decennial period.

The immediate exciting cause of the disease is most commonly involved in obscurity, sometimes it may be traced to a blow on the head, a fall or concussion, or to excessive drinking; but more frequently the symptoms manifest themselves suddenly, without being in any way attributable to such external influences, and occur in vigorous and apparently healthy persons.

The pressure exercised by an aneurismal sac situated within the cranium is almost exclusively directed against the yielding cerebral substance, which is often extensively disorganised; the bones of the skull, however close their proximity to the sac may be, frequently escaping, and seldom suffering much. This peculiarity in the effects of aneurism in this situation may be partly owing to the very dense and compact character of the inner table of the skull, but is, doubtless, principally due to the very soft and yielding nature of the contents of the cranium. Absorption of the subjacent bone, however, sometimes takes place to a limited extent: thus in one case the body of the sphenoid bone was indented and partially absorbed.

The parts compressed will necessarily vary according to the situation of the tumor; but those that principally suffer are those seated at the base of the brain, and forming the floor of the lateral ventricles. In Moore's case one of the optic nerves was flattened by the pressure of the substance of the anterior lobe, the laminae perforated the roots of the olfactory tract, the anterior part of the corpus striatum, and a considerable quantity of the neighbouring white matter of the anterior lobe was removed. In a case by Dr. Eager (*Ranking*, vol. vi.) the portio dura of the right side was paralysed from this cause. In Mr. Smith's case (*Dub. Journ.* vol. xxv.), the floor of the ventricle, the tuber cinereum, and origin of the optic nerve suffered.

Rupture of the sac usually takes place by a gradual thinning of one part of it, which at last gives way by a rent or fissure, the blood being effused either at the base of the brain into the arachnoid cavity and the meshes of the pia mater, or into the lateral ventricles, either directly, or by breaking through an intervening portion of cerebral substance.

Besides the changes that take place in the cerebral substance as the result of pressure, important lesions may be met with as the effect of the interruption that the pressure of the aneurism offers to the circulation in, and nutrition of, the cerebral hemispheres. Thus in the case of aneurism of both internal carotids that has already been referred to as occurring at University College Hospital, there was white softening of both the anterior cerebral lobes, and this lesion was most marked on that side that corresponded to the largest aneurism, and where consequently it may be supposed the greatest amount of obstruction to the circulation existed.

The symptoms of aneurism within the cranium are extremely equivocal, and indeed aneurisms of large size may exist at the base of the brain without occasioning any symptoms whatever. An interesting instance of this occurred at University College Hospital in 1848. A man, fifty-seven years of age, died of pulmonary apoplexy and

chronic pneumonia of the left lung, consequent upon the pressure of an aneurism of the commencement of the descending aorta on the pulmonary veins of that side. On examining the head after death, an aneurism of the basilar artery as large as a hazel nut was met with, of which no suspicion had been entertained during life, there having been no head symptoms whatever. The sac of the aneurism was very thin, and there was much atheroma in the vertebrae.

The only symptoms that are of constant occurrence when this disease goes on to a fatal termination, are those of hemiplegia and apoplexy. These may come on suddenly without any previous warning, or may be preceded by a train of phenomena indicative of the existence of chronic disease within the cranial cavity.

The most constant of these symptoms is pain, which offers, however, great variety, in seat, extent and character. It may be diffused or occupy a fixed point; it may be continuous or intermitting; increased by movement, accompanied by peculiar sensations, such as pulsation or of opening and shutting of the top of the cranium.

The sight and hearing are often impaired; dimness of sight, dilatation of one or both pupils, photophobia, diplopia, and loss of vision have been noticed in several of the cases recorded. Ptosis may likewise be met with. Buzzing noises in the ears and deafness are also not uncommon symptoms. Deafness more particularly appears to be of frequent occurrence.

The patient rarely loses the power of articulation and of deglutition; imperfect speech and dysphagia have however occurred.

There may be paralysis of the side of the face, shaking palsy, or complete hemiplegia, or fits of an epileptic nature may occur. The mental condition may undergo changes indicative of chronic disease of the brain. There may be depression of spirits, listlessness, or, as was noticed in the case above related, the temper may become irritable, and the patient may be garrulous or silly. Insanity has been noticed in one case, and, as is usually the case in cerebral affections, the gastric functions are often impaired.

But very frequently no premonitory symptoms of any kind manifest themselves, the patient being suddenly seized, when apparently in good health, with apoplexy, which terminates rapidly in death.

In some cases the presence of the aneurism has been detected by a rough "whizzing" noise being heard on the application of the stethoscope over one side of the head, and perhaps being audible to the patient. This sign, however, occurs in but few cases, but when it does occur is unquestionably the most pathognomonic of all. I am not aware that it has been met with in any form of cerebral disease except intracranial aneurism.

Thus it will be seen by a reference to this list of symptoms that, with the exception of the whizzing noise, no special signs are afforded by aneurisms within the skull which will enable us to distinguish between the symptoms occasioned by their presence, and those of other tumors of the brain, and of organic cerebral disease.

The fatal termination may occur from one of four causes:—

1. The tumor may exercise such pressure upon the whole cerebral mass as to occasion death. This mode of termination is rare, and I am only ac-

quainted with one case of this description, which is reported by Dr. Ruschenberger in the *American Journal*, Jan. 1846. The symptoms in this case were very remarkable, consisting of complete hemiplegia of the left side, with involuntary antero-posterior vibration of the head and body, and paralysis agitans of the right leg. He slept heavily, with loud snoring; ate voraciously, but had considerable difficulty occasionally in deglutition and in articulation. The intellect was clear, but very slow. After death, an aneurism of the basilar artery as large as a pigeon's egg, and containing an irregular, very hard, dry clot of blood, was found. The sac had given way at one point, extravasation taking place into the substance of the Pons Varolii, which was softened, and of a black colour.

2. The most frequent mode in which death takes place in these cases is by the sudden rupture of the sac, and the extravasation of its contents into the cavity of the arachnoid at the base of the brain, or into the lateral ventricles. This latter takes place either from the aneurism projecting into them, and there giving way or rupturing into these cavities by breaking down the intervening cerebral substance. When this mode of termination occurs there are occasionally no warning or premonitory symptoms of any impending danger; the patient being, apparently in good health, struck down by an attack of apoplexy which is speedily fatal. More frequently a series of those symptoms that have already been mentioned as attending many cases of this disease preceded the fatal event for a longer or shorter time. When rupture of the sac and extravasation of blood takes place, death is inevitable; at least I am not acquainted with any case in which the appearances found after death could lead me to the belief that this condition had been even temporarily recovered from.

3. Death may result from another cause than pressure of the aneurismal sac, or its rupture and the extravasation of its contents—viz. from softening or disorganisation of the substance of the brain to a greater or less extent, in consequence of the obstruction offered to the passage of the blood through the aneurismal vessel. In the case of aneurism of both carotids, already mentioned as having occurred at University College Hospital, this was the case; both anterior cerebral lobes were affected with white softening, and this condition was especially observable on that side on which the aneurism was largest.

4. Lastly, death may be produced by the irritation occasioned by the presence of one or more aneurismal tumors within the cranium. Of this an interesting example is offered by the history of a case of aneurism of both internal carotids contained in the Museum of the College of Surgeons, and related by Sir G. Blanc (*in the Trans. of the Society for the Improvement of Medical and Chirurgical Knowledge*, vol. ii. p. 192). In this case the patient, a lady, sixty-nine years of age, had suffered for four years from attacks of giddiness, headache, and imperfect vision; about sixteen months before her death she became insane, recovered, and then relapsed twice in the same state. After having regained her senses for some months, she became affected with giddiness, redness of the eyes, and maniacal delirium, with fever, which continuing for some months, caused her death.

After death, the following appearances were

found:—"Upon examining the body, there was no appearance in the brain itself that could in any way account for the symptoms. There was, indeed, a greater quantity of fluid than common in the ventricles, and the surface of it was moister than it is usually found in a sound state; but in all other cases which have occurred to me of organic affections of the brain proving fatal, except those which are sudden, such as apoplexy, there has been a preternatural quantity of fluid in its ventricles. There were also spicula of bone in the membrane forming the falx. The inner substance of the crura cerebri was of a brown colour, and more tender than natural. The optic nerves were smaller than natural, as if they had been wasted. The septum lucidum was more more than usually dense.

"But the morbid appearance in this case, which was so singular, and to which the symptoms of complaint seem chiefly referrible, was two bulbs, about five-eighths of an inch in diameter, filling up the hollow on each side of the sella turcica, which were evidently dilatations of the carotid arteries, and, from their being filled with laminae of coagulated blood, there could be no doubt of there being aneurisms of these arteries. The dissection was made by Mr. Hunter, assisted by Mr. Home, in the presence of Dr. Jenner and myself, and all concurred in the opinion that these tumors were aneurisms. The one on the left side was largest. That on the right side communicated with the cavity of the artery, which was not the case with the other."

In the treatment of intracranial aneurism there is usually little to be done. The nature of the case not being sufficiently obvious, in the majority of cases, to justify active measures. Should, however, the loud rough whiz be distinctly audible to others, besides the patient, over one side of the head, and more especially about the base of the cranium, or by application of the stethoscope to the mastoid process, ligature of the carotid artery on the affected side might with propriety be practised. This has been successfully done in a most interesting and instructive case of intracranial aneurism, by Mr. Coe, of Bristol, and reported by him in the *Association Journal*, Nov. 9, 1855.]

ANEURISMAL VARIX; VARICOSE, OR VENOUS ANEURISM; ANEURISM BY TRANSFUSION.

By these terms surgeons mean a tumor arising from a preternatural communication formed between a large vein and a subjacent artery. Thus, in venesection, performed immediately over the artery, at the bend of the elbow, if the lancet be carried too deeply, it may transfix the vein, and wound the artery; in which event, the arterial blood, in consequence of the proximity of the two vessels, instead of being effused in the areolar tissue, will pass directly into the cavity of the vein, which will become dilated in the form of a varix by the jet of arterial blood into it.

Although Sennertus probably referred to an instance of this disease (op. t. v. l. v. cap. 43), Dr. W. Hunter is undoubtedly the first who gave an accurate description of it. Scarpa is disposed to claim a share of the merit for his countryman Guattani; but, as Mr. Hodgson has remarked, Dr. Hunter's observations on this disease were published in the years 1757 and 1764; whereas, Guattani did not see his first patient until the

year 1769, and his book was not published until the year 1772.

"Does it ever happen in surgery," says Dr. Hunter, "that when an artery is opened through a vein, a communication, or anastomosis, is afterwards kept up between these two vessels? It is easy to conceive this case; and it is not long since I was consulted about one that had all the symptoms that might be expected, supposing such a thing to have actually happened, and such symptoms as otherwise must be allowed to be very unaccountable. It arose from bleeding; and was of some years' standing when I saw it, about two years ago, and I understand very little alteration has happened to it since that time. The veins at the bending of the arm, and especially the basalic, which was the vein that had been opened, were there prodigiously enlarged, and came gradually to their natural size, at about two inches above, and as much below the elbow. When emptied by pressure, they filled again almost instantaneously; and this happened even when a ligature was applied tight round the forearm, immediately below the affected part. Both when the ligature was made tight and when it was removed they shrunk, and remained of a small size, while the finger was kept tight upon the artery, at the part where the vein had been opened in bleeding. There was a general swelling in the place and in the direction of the artery, which seemed larger and beat stronger than what is natural; and there was a tremulous jarring motion in the vein, which was strongest at the part which had been punctured, and became insensible at some distance, both upwards and downwards." (*Med. Obs. and Inq.* vol. i.)

In the second vol. of the same work, Dr. Hunter adds some further remarks:—"In the operation of bleeding, the lancet is plunged into the artery through both sides of the vein; and there will be three wounds made in these vessels, viz. two in the vein and one in the artery, and these will be nearly opposite to one another and to the wound in the skin. This is what all surgeons know has often happened in bleeding, and the injury done the artery is commonly known by the jerking impetuosity of the stream whilst it flows from the vein, and by the difficulty of stopping it when a sufficient quantity is drawn.

"In the next place, we must suppose that the wound of the skin and of the adjacent or upper side of the vein heal up as usual; but that the wound of the artery and of the adjacent, or under side of the vein, remain open (as the wound of the artery does in the spurious aneurism), and by that means the blood is thrown from the trunk of the artery directly into the trunk of the vein. Extraordinary as this supposition may appear, in reality it differs from the common spurious aneurisms in one circumstance only; viz. the wound remaining open in the side of the vein as well as in the side of the artery. But this one circumstance will occasion a great deal of difference in the symptoms, in the tendency of the complaint, and in the proper method of treating it: upon which account the knowledge of such a case will be of importance in surgery. It will differ in its symptoms from the common spurious aneurism, principally thus:—The vein will be dilated, or become varicose, and it will have a pulsating jarring motion, on account of the stream from the

artery. It will make a hissing noise, which will be found to correspond with the pulse for the same reason. The blood of the tumor will be altogether or almost entirely fluid, because kept in constant motion. The artery, I apprehend, will become larger in the arm and smaller at the wrist than it was in the natural state; which will be found out by comparing the size and the pulse of the artery, in both arms, at these different places, the reason of which I will speak of hereafter; and the effects of ligatures, and of pressure upon the vessels above the elbow and below it will be what every person may readily conceive who understands any thing of the nature of arteries and veins in the living body.

"The natural tendency of such a complaint will be very different from that of the spurious aneurism. The one is growing worse every hour, because of the resistance to the arterial blood, and if not remedied by surgery must at last burst. The other, in a short time, comes to a nearly permanent state; and, if not disturbed, produces no mischief, because there is no considerable resistance to the blood that is forced out of the artery.

"The proper treatment must, therefore, be very different in these two cases; the spurious aneurism requiring chirurgical assistance, as much, perhaps, as any disease whatever; whereas, in the other case, I presume it will be best to do nothing.

"If such cases do happen, they will no doubt be found to differ among themselves in many little circumstances, and particularly in the shape, &c. of the tumefied parts. Thus the dilatation of the veins may be in one only, or in several, and may extend lower or higher in one case than in another, &c., according to the manner of branching, and to the state of the valves in different arms. And the dilatation of the veins may also vary, on account of the size of the artery that is wounded, and of the size of the orifice in the artery and in the vein.

"Another difference in such cases will arise from the different manner in which the orifice of the artery may be united, or continued with the orifice of the vein. In one case, the trunk of the vein may keep close to the trunk of the artery, and the very thin stratum of areolar tissue between them may, by means of a little inflammation and coagulation of the blood among its filaments, as it were, solder the two orifices of these vessels together, so that there shall be nothing like a canal going from one to the other; and then the whole tumefaction will be more regular, and more evidently a dilatation of the veins only. In other instances, the blood that rushes from the wounded artery, meeting with some difficulty of admission and passage through the vein, may dilate the cellular membrane between the artery and vein into a bag, as in a common spurious aneurism, and so make a sort of canal between these two vessels. The trunk of the vein will then be removed to some distance from the trunk of the artery, and the bag will be situated chiefly upon the underside of the vein. The bag may take on an irregular form, from the areolar tissue being more loose and yielding at one place than at another, and from being unequally bound down by the fascia of the biceps muscle. And if the bag be very large, especially if it be of an irregular figure, no doubt coagu-

lations of blood may be formed, as in the common spurious aneurism."

A concurrence of two circumstances is requisite for the production of an aneurismal varix: 1. The puncture in the vein, and that in the artery, must be exactly in the same direction; 2. The solution of continuity in the integuments and upper side of the vein must heal, while the wound in the deeper side of that vessel, and the puncture in the upper surface of the artery, remain open, and communicate so readily that the arterial blood finds greater facility in entering from the artery into the vein, than in being effused from the artery into the surrounding areolar tissue.

If one of these two circumstances be wanting, either because the wounding instrument has entered the artery a little obliquely from the vein, or because the vein has not been sufficiently near to the artery, on account of the areolar tissue between them, the arterial blood most frequently does not produce the aneurismal varix; or, if it does, the disease is always complicated with effusion of arterial blood into the areolar tissue, or with an aneurism and aneurismal varix at the same time. In this case, the small aneurismal sac serves as a short canal of communication between the artery and the vein (*Med. Facts and Obs.* vol. iv. p. 115); two distinct diseases, in fact, being formed from the same cause, and placed one over the other, viz. an aneurism and an aneurismal varix. (*Scarpa*, p. 421, ed. 2.) The following marks of distinction between aneurism and aneurismal varix are pointed out by the same author; the aneurismal varix always forms a circumscribed tumor; aneurism does not always do so. The areolar tissue, which constitutes the sac of the aneurism, does not always resist so strongly the impetus of the arterial blood as the coats of the vein do. Not unfrequently, therefore, aneurism, from being *circumscribed* at first, becomes *diffused*; extends along the course of the wounded artery; compresses strongly the surrounding parts; occasions acute pain and inflammation; and the parts are threatened with gangrene. On the contrary, the aneurismal varix is always *circumscribed*, increases very slowly, does not produce much pain, and as it augments it always extends more or less above or below the place where venesection has been done; and this extension is in proportion to the greater or less force with which the arterial blood is thrown from the artery into the vein, and the greater or less resistance made by the valves situated in the vein below the puncture; and according to the greater or less number of veins communicating with the aneurismal varix. The seat of the disease is generally the basilic or median basilic vein, which appears dilated in an unusual manner, forming an oblong tumor of the size of a walnut, if the disease is recent. In the centre of the swelling is the cicatrix left by the lancet. The vein is less dilated the further it is from this scar; and, in general, at the distance of two inches and a half above and below this point the vessel resumes its natural size. The small tumor, as has been explained, pulsates like an artery, with a tremulous motion and hissing noise, which is sometimes so great that the patient cannot sleep, if he is lying with his head low, and resting on the injured arm. The trunk of the brachial artery, from the axilla down to the place where it has been wounded with the lancet, vibrates with extraor-

dinary force. There is no change of colour, nor inflammation of the skin; and the pain is inconsiderable. The swelling is compressible and yielding; but it returns as soon as the pressure is removed from it. When the arm is kept for some time raised up towards the head, the tumor diminishes; and the same thing happens when pressure is made on the communication between the artery and vein, or when a tight tourniquet is applied near the axilla. If the disease be complicated with aneurism, a second pulsating tumor will be found lying under the aneurismal varix. (*Scarpa*, p. 424, ed. 2.)

A simple aneurismal varix is gradual in its formation, never attaining a considerable size, and never exposing the patient's life to danger by the rapidity of its increase, or a tendency to burst; but, if it be a less serious disease in these respects than a consecutive false aneurism, it does not, like the latter, present any chance of a spontaneous cure, and its duration is perpetual. However, after it has acquired some size, and the veins have become exceedingly varicose, the patient complains of numbness and weakness of the limb, diminution of its temperature; and there is a bluish, or somewhat purple, discoloration of it, which Breschet ascribes to the passage of some of the venous blood into the artery, and to there being a smaller quantity of scarlet blood conveyed by the artery into all parts beyond the tumor. (*Mém. Chir. sur Différentes Espèces d'Aneur.* p. 102.)

It is generally believed that only the blood of the artery leaves its proper vessel; but, according to the investigations of M. Breschet, at the same time that arterial blood passes into the veins the artery itself receives a certain quantity of venous blood. The symptoms, he observes, demonstrate this during life, as well as the examination of the parts after an operation on the tumor: it is also proved by the appearances of the vessels in *post mortem* examinations. (*Breschet, Mém. sur Différentes Espèces d'Aneurysmes*, p. 100.)

After relating two cases, illustrative of the nature of aneurismal varix, Dr. W. Hunter proceeds to inquire, "Why is the pulse at the wrist so much weaker in the diseased arm than in the other?—surely the reason is obvious and clear. If the blood can easily escape from the trunk of the artery directly into the trunk of the vein, it is natural to think that it will be driven along the extreme branches with less force, and in less quantity.

"Whence is it that the artery is enlarged all the way down the arm? I am of opinion, that it is the consequence of the blood passing so readily from the artery into the vein, and is such an extension as happens to all arteries, in growing bodies, and to the arteries of particular parts when the parts themselves increase in their bulk, and at the same time retain a vascular structure." (See *Med. Obs. and Inq.* vol. ii.) This explanation is not deemed by Breschet altogether correct. M. Breschet has endeavoured to give a more particular and precise explanation of the changes which the vessels and adjacent textures undergo, and the effects of the communication between the arteries and veins. In consequence of the artery receiving venous blood, the flow of this fluid through it becomes slower, and the pulse weaker. The artery itself dilates throughout its whole extent, a fact long ago noticed by Morand; its tunics grow thinner, and become nearly as soft and flaccid as those of a vein,

The artery becomes likewise tortuous, and gradually assumes the characters, first, of a vein, and then of a dilated vein. All this happens, however, only below the communication between the two vessels. (*Breschet, Mém. Chir. sur Différentes Espèces d'Aneur.* p. 103.) If it were not for the passage of some of the blood of the vein into the artery, Breschet conceives, that it would be impossible to account for the diminished rate of the circulation in the latter vessel, the reduction of sensibility and temperature of the limb, and especially the enlargement of the artery beyond the tumor, its assuming the characters of a vein, and the deeper colour of the blood in it. The vein, likewise, becomes altered around the wound (below, and particularly above it), its coats assuming greater solidity and firmness: and though the vessel is enlarged, the suppleness of its parietes is diminished. (See *Breschet, op. cit.* p. 104.)

No doubt M. Breschet has extended his criticisms of Dr. Wm. Hunter's account too far, inasmuch as the atrophy and loss of temperature in the extreme part of the limb are certainly, in some measure, owing to a part of the arterial blood flowing directly and prematurely into the venous system. Dr. Wm. Hunter has chiefly erred in overlooking the effect of the entrance of venous blood into the artery. If, as Hunter states, a greater quantity of blood arrives by the artery above the wound, how does it happen, inquires M. Breschet, that the artery should diminish in diameter below the puncture, as Dr. Wm. Hunter affirms that he had ascertained to be the case at the wrist? "For (observes M. Breschet), by the more considerable afflux of red blood, the lower continuation of the artery must be indemnified for the quantity of this fluid which passes into the vein. *A new channel, opened for the arterial blood, cannot (says he) bring on a dilatation of the vascular trunk above the aperture of the new channel.* This effect would be more likely to arise from some impediment to the circulation, and is actually what does happen in old consecutive false aneurisms." (See *Mém. sur les Différentes Espèces d'Aneur.* p. 105.) M. Breschet, further on, expresses a suspicion, that Dr. Wm. Hunter perhaps confounded the weakness and softness of the pulse at the wrist with a diminution of the artery. I am of opinion that little foundation exists for this suspicion, because it is certain that, in some cases of aneurismal varix, the arteries below it, so far from being enlarged, are diminished; and therefore correspond to Dr. Wm. Hunter's description. In proof of this fact, I may refer M. Breschet to the evidence of his distinguished countryman, M. Jules Cloquet, who has given the particulars of the dissection of an aneurismal varix illustrated by a diagram (pl. 1, fig. 13), where the brachial artery below the tumor was not larger than the middle portion of the radial artery. (See *Jules Cloquet, Pathol. Chir.* p. 85, 4to. Paris, 1831.) According to M. Breschet, in old varicose aneurisms of the limbs, and especially of the lower extremities, the principal artery, as well as its branches, are manifestly dilated, and their coats resemble those of veins. "If the same quantity of red blood passed through a vessel of this description, its pulsations would not have the same character as those of the artery of the opposite limb. We think, then, that this change in the pulsations of the artery in old aneurisms depends both upon the dilatation of the vessel, de-

monstrated in the dead subject, and upon the passage of venous blood into the artery; for how could dilatation and alteration of the parietes of the vessel be accounted for in any other way?"

In the foregoing passage, the statement that a new channel for the blood, arising from an arterial trunk, will not be followed by an enlargement of that trunk above such channel, seems to me incorrect; for if there be a new channel, blood will be required for it: an increased quantity will therefore pass through the trunk above the new channel, and such trunk of course increase in size, agreeably to a well-established law of the animal economy. The case of an old false aneurism, referred to by M. Breschet, seems to me rather to invalidate than strengthen his conclusion, respecting the cause of the enlargement of the arterial trunk above the disease. This change is not ascribable to impediment of the circulation, but to the blood having new channels to supply: viz. the sac, and the enlarged collateral anastomosing vessels.

An interesting circumstance, pointed out by M. Breschet, is, that the dilatation of the artery beyond the injury, is not exemplified in all varicose aneurisms. Their situation has considerable influence in producing it; for it can only take place in vascular trunks of large calibre; and it is requisite also that venous blood pass into the artery, and that the circulation of this fluid be favoured by the laws of hydraulics and the power of gravitation. Hence, this dilatation of the injured artery, regarded by M. Breschet as the consequence of the admission of a certain quantity of venous blood into it, is principally noticed in varicose aneurisms of the limbs, and not in those of the neck, or subclavian region. The wound in the artery must likewise have a certain extent, be constantly gaping, and in direct communication with the vein. (See *Breschet in Mém. sur Différentes Espèces d'Aneur.* p. 107.) In the remarkable case of spontaneous varicose aneurism of the thigh, recorded by Mr. Perry, the posterior tibial artery and the other arteries in the neighbourhood of the aneurism were apparently sound, (See *Lond. Med. Gaz.* Nov. 1835.)

In thin subjects, the median basilic vein is so close to the brachial artery, the track of which it crosses at a very acute angle, that it is almost impossible to open it at this point, without risk of wounding the artery at the same time. Although the bend of the arm is the situation in which the aneurismal varix and venous aneurism are usually noticed, it is easy to conceive that they may happen wherever an artery of a certain diameter lies immediately under a large vein. Thus, Lassus saw an aneurismal varix in the ham, the consequence of a wound with a sword, which had transfixed the popliteal vein and artery. (*Méd. Opér.* t. ii. p. 442.) Breschet records instances of it at the upper and inner part of the arm; in the thigh; and in the neck, from a communication formed between the common carotid and the internal jugular vein, by a wound. He likewise gives the particulars of several occasioned by venesection at the bend of the arm, the ordinary situation of the disease. Larrey records examples of it in the subclavian vessels, the external iliac, the popliteal, and between the carotid artery and internal jugular vein. (*Mém. de Chir. Clin.* t. iii.)

The frequency with which Dupuytren met with these arterioso-venous aneurisms, as he terms them,

was considerable; for, during fifteen years, not a single year passed without his being consulted for at least two cases. For the prevention of them, he recommends the following rules:—1. That venesection should never be practised until the pulsation of the artery is felt. 2. That the vein immediately over the artery should never be punctured. 3. That some other vein should be selected. He admits, however, that other veins sometimes cannot be readily found, and that they do not always yield the requisite quantity of blood; still he deems these inconveniences slight, in comparison with that of exposing the patient to a wound of the artery. (*Dupuytren, Clinique Chir. t. i. p. 262.*) While I fully coincide with this eminent surgeon, in recommending a vein to be generally preferred which does not lie directly over the artery, I do not agree with him that the practitioner should not open the median basilic vein, if another could not be easily found which would furnish the proper quantity of blood. I frequently bleed in the median basilic vein; and as there is the fascia between it and the artery, believe, that the latter vessel can only be wounded by a very careless or unskilful hand. Indeed, when Dupuytren, in censuring the custom of letting perfect novices in the profession attempt venesection (p. 261), he is adverting to the chief cause of the accident. The last case which I saw, was in a woman who had been bled by a farrier.

Baron Larrey, surgeon to the hospital at Toulouse, saw a case of aneurismal varix, which had been occasioned by a wound of the popliteal vein and artery; and a history of the disease, accompanied with the pathological preparation, was sent to the former Royal Academy of Surgery at Paris. "The varicose swelling, which was as large as two fists, occupied the whole of the ham in a middle-aged man, who some years previously had been wounded with a sword in that part of the limb. At a consultation, amputation was deemed necessary, and was performed with success. At the bottom of the varicose pouch, the communication between the popliteal vein and artery was observed. The sac itself was evidently composed of the vein, the parts of which, adjacent to the varicose swelling, were dilated, especially the lower continuation of the vessel. The popliteal nerve was rendered flat, like a piece of tape, and adherent to the outside of the cyst." (See *Mém. de Chir. Mil. t. iv. p. 340*; *Boyer, Traité des Mal. Chir. &c. t. ii. p. 177.*)—Two cases are likewise recorded by Mr. Hodgson. In one, the disease was caused in the thigh, about four inches below Poupert's ligament, by the point of a heated iron rod, which had passed through the femoral artery and vein. In the other example, the aneurismal varix was situated in the ham, and was the consequence of a wound in that part with a pistol-ball. (*On the Diseases of Arteries, p. 498.*) Larrey records one example of aneurismal varix situated under the clavicle.

P. Cadrioux was wounded with a sabre in a duel, on the 20th of November, 1811: part of the attachment of the sterno-mastoid muscle was divided, the anterior scalenus, the subclavian artery and vein at a very deep point, and probably also a portion of the brachial plexus. A most violent hemorrhage took place, followed by syncope. Pressure was applied to the wound, and the patient conveyed to the hospital at Gros Caillou. The external wound, which was small,

did not bleed at all the following morning; but the clavicle was quite concealed by a large tumor, which throbbed with the arteries, particularly at its lower part. A peculiar noise, like that of the passage of a fluid through tortuous metallic tubes, could also be felt more deeply in the direction of the axillary vein. The arm was quite cold, insensible, motionless, and without any pulse even in the axillary artery itself. On the 22nd, the tumor was not larger, but its throbbings were stronger; the jugular vein on the same side was considerably dilated; and the pulsation of the carotid, and of the arteries of the opposite arm, had augmented. A vein in the right arm was opened, and compresses dipped in camphorated vinegar, muriate of ammonia, and ice, applied to the swelling. It would be superfluous here to detail the diet, bleedings, and other parts of the treatment. On the eighth day, the outer wound was quite healed. On the tenth, the veins of the limb were observed to be swelled, and sensibility and warmth were returning in it; though no pulse could yet be felt. The tumor was much smaller, and restricted to a circumscribed place behind the great pectoral muscle; but the hissing sound was still plainer. By degrees, the muscles of the arm and forearm regained their power of motion. The hand, however, continued useless, and affected with pricking pains. On the twentieth day, the tumor was quite gone; but the hissing sound was unaltered, and the throbbings were still evident in the veins of the neck and arm. The arm was not at all emaciated. On the fifty-fifth day, a pulse at the wrist could be slightly felt: the hissing sound had become less distinct; the veins were less turgid and their throbbing had diminished. A second instance of aneurismal varix, or, rather, perhaps, of a varix of all the veins of the arm, caused by a sword-wound of the axilla, is recorded by Larrey. In the most prominent of the large vessels there was a pulsation. (*Mém. de Chir. Mil. t. iv. p. 341, &c.*)

Dr. Dorsey, of Philadelphia, published a case of aneurismal varix, which is in several respects interesting. A patient was wounded in the leg with buck-shot; and after the cure of the injury, an aneurismal varix was noticed just below the knee; and in a little time the superficial veins of the limb became dilated, and the hissing noise, characterising this species of aneurism, could be plainly distinguished. The patient was seen by Dr. Dorsey, twelve years after the accident; the veins were then considerably distended from the toes up to the groin, all about which latter part pain was constantly experienced, and some ulcers situated on the foot and ankle could not be healed by any of the remedies which were tried. The patient was under the care of Drs. Physick and Wistar. The enormous distension of the vessels of the leg, and the uncertainty of finding out the communication between the artery and vein, led these gentlemen to tie the first of these vessels in the middle of the thigh. Gangrene soon ensued, and in this state the patient was further weakened by an unexpected hemorrhage from one of the distended veins; and though the vessel was secured with a ligature, the bleeding recurred, the patient became more and more enfeebled, and at length expired. When the limb was examined after death, the whole of the trunk of the femoral artery was found preternaturally dilated, while all the veins

of the limb were considerably distended; a bougie could readily be passed from the popliteal into the posterior tibial artery which participated in the dilatation, and from this last artery the instrument could be passed into the vein, through a cyst situated on the inside of the leg below the knee. (See *Dorsey's Elements of Surgery*, vol. ii. p. 210. Philadelphia, 1813.)

In November, 1835, Mr. Perry, surgeon to the Marylebone Infirmary, communicated to the Royal Medical and Chirurgical Society of London, the history of a remarkable case of varicose aneurism. It was a case in which death ensued six days after an operation for aneurism of the femoral artery, in consequence of the sac having communicated with the accompanying vein. I believe this patient was shown to me some months before the operation, when, from the peculiar thrilling sensation and hissings then perceptible, I intimated my expectation, that a communication existed between the femoral vein and the artery. This is not the only instance on record, where a similar condition was spontaneously established between a great vein and a neighbouring artery, for Mr. Syme, of Edinburgh, has published the particulars of a case, in which a free communication was found between the descending vena cava and the aorta, close to the bifurcations, attended with a considerable swelling of the latter vessel. (See *Edin. Med. and Surgical Journ.* No. 108.)

Professor Scarpa, Dr. Hunter, B. Bell, Pott, and Guattani, mention cases of aneurismal varix, which remained stationary for fourteen, twenty, and thirty-five years. Several cases are related by Brambilla, Guattani, and Monteggia, of a cure having been obtained by means of compression. But, as this method of cure, if it does not succeed, exposes the patient to the danger of a complication of the disease with an aneurism, it ought not to be employed, except in recent cases, where the tumor is small, and in slender patients. Sir Astley Cooper mentions in his Lectures, that he once cured an aneurismal varix in a young lady, by compression with an instrument; and in the Museum of University College is a preparation, given to that institution by Mr. Oldknow, illustrating the power of pressure to effect a cure, even when the disease consists of a varix and a false aneurism together. In this preparation, the communication between the vein and the subjacent aneurism, and that between the aneurism and the artery, are obliterated; while the remains of a small sac are discernible between the artery and vein. The case was treated by Mr. Oldknow. I have seen one example cured by compression; the case was recent, and in a woman about forty, who had imprudently suffered herself to be bled by a farrier.

Two cases are recorded, in which it was necessary to operate in consequence of the disease being joined with aneurism of the artery, and even bursting. The sacs were opened, and a ligature applied both above and below the aperture in the artery. (See *Park*, in *Medical Facts and Obs.* vol. iv. p. 111; and *Physick*, in *Medical Museum*, vol. i. p. 65.) The latter form of the disease, which is particularly noticed by Dr. Hunter, and also by my friend Mr. Hodgson, is readily understood by recollecting, that the artery and vein, when punctured together, do not always unite in such a manner as to let the arterial blood have a direct

passage into the vein; but they may be separated for some distance from each other, so that the blood passes from the artery into the adjacent areolar tissue, where a sac is formed, into which the blood is poured previously to its entrance into the vein. (See *Gibson's Institutes of Surgery*, vol. ii. p. 158. Philadelphia, 1825.)

In the winter of 1819, I heard a case read to the Medical and Chirurgical Society of London, from Mr. Atkinson of York, who had found it necessary to take up the brachial artery, on account of the large and increasing size of an aneurismal varix; mortification of the limb ensued. In the Museum of University College is a preparation taken from a person on whom Sir Charles Bell operated for a venous aneurism, and who died of gangrene of the limb. In this case, there was a high bifurcation of the brachial artery, and the radial division had been punctured in bleeding. The preparation exhibits a double aneurism; one being under the fascia, and communicating with the dilated portion of the vein through an opening in that texture. An anastomosing branch, between the radial and ulnar, is seen equal in size to either of them. I believe that the records of surgery prove, that operations for the cure of venous aneurisms have more frequently been followed by mortification than operations for other aneurisms; and when it is considered, that the extreme part of the limb, even previously to the ligature of the artery, is deprived of a great quantity of the arterial blood, which ought to be distributed to it, that venous blood gets into the artery, and that it has a difficulty in maintaining its proper temperature, the fact seems accounted for. These considerations, joined with the recollection that the disease, after attaining a certain size, generally remains stationary through life, ought to make surgeons decline an operation, except when the increase of the false aneurism, or an unusual degree of annoyance from the swelling, justifies the opposite line of conduct. Here the artery, then, has a ligature applied to it under very disadvantageous circumstances. When an arterial trunk is tied, soon after the wound of an artery, as M. Breschet observes, hopes may be entertained of the member preserving its vitality, because its several textures are in a favourable state for receiving blood from the vessels of small calibre. The anastomoses between the trunk of the vessel, above and below the ligature, possess the advantage of having the lower portion of the artery sound, and fitted for carrying on the circulation. But when a ligature is applied to an artery for venous aneurism of long standing, the part of the artery situated below the disease is dilated; its coats are weakened; they no longer possess the contractility requisite to carry on the circulation; and the vitality of the tissues being thus reduced, the fluids stagnate in them and the parts are soon seized with gangrene or paralysis. (See *Mém. Chir. sur Différentes Espèces d'Aneurysmes*, p. 109.) If the limb be not seriously affected with atrophy, and a diminution of its temperature, sensibility, and power of action, the wisest plan is to let the disease alone, or, at most, only to make gentle equable pressure on the limb, and on the point corresponding to the wound of the artery. In the opposite circumstances, says M. Breschet, a surgical operation is indicated, which should not consist in the simple ligature of the artery between the heart and the wound, because the return of

the blood through the lower portion of the artery would reproduce the disease, especially if the wound were not recent. Neither, says he, should it consist in merely tying the artery beyond the injury, or in the separate ligature of the vein above it, because these proceedings would expose the patient to the risk of various inflammatory accidents, or to a false aneurism, either circumscribed or diffused. But it is better and safer to place the injury of the vessels between two ligatures. By acting in this manner, not only do we hinder the blood from returning through the lower end of the artery and reproducing the disease, but we prevent the venous blood from passing into the artery, and thereby avert the stupor which the passage of this black blood into the tissues always creates; a stupor the more considerable, and the more readily followed by gangrene, inasmuch as the red blood enters the organised textures in less quantity, and with increased difficulty. (See *Breschet*, in *Mém. sur Différentes Espèces d'Aneurysmes*, p. 153.) If the artery be tied both above and below the communication with the vein, the exchange of blood between the two vessels will be effectually stopped: the proposal once made by Dupuytren, to include the vein in the ligatures along with the artery, must therefore be unnecessary, and, as likely to cause phlebitis, it should not be adopted. Indeed, Dupuytren himself never tried the plan on the living subject. (See *Malgaigne*, *Manuel*, &c. p. 195.) As for the mode of operating different writers give different advice. Thus, according to Scarpa, when the aneurism is joined with an aneurismal varix, and circumscribed, but the circumstances such as to require the brachial artery to be tied, this vessel should be exposed, and tied above the swelling with a single ligature. It is only when the aneurism is diffused that opening the swelling and applying a ligature both above and below the aperture in the artery, are deemed by him necessary. On the other hand, Mr. Guthrie directs "an incision at the part, and the application of two ligatures to the artery, for although in some cases one has been found sufficient, in others the blood has returned into the sac by the anastomosing branches, and a second operation has been required to effect a cure." (See *Guthrie*, *On Dis. of Arteries*, p. 334.) M. Lisfranc prefers opening the sac, and applying two ligatures. "Perhaps," says he, "in examples where a sac intervenes between the dilatation of the vein and the injury of the artery, it might be prudent to open the aneurismal pouch without meddling with the vein; a method that would create less risk of phlebitis, which sometimes arises as a complication of the operation." (*De l'Obli-tération des Artères dans les Aneurysmes*, p. 112, 8vo. Paris, 1834.) In three subjects, in whom the brachial artery was tied, the tumor reappeared (*Dupuytren*, *Breschet*); and in two others, in whom the femoral artery was tied, death ensued from sloughing and hemorrhages. M. Jules Cloquet relates a case where the ligature of the artery above the communication with the vein was followed by a return of the pulsation in the tumor, atrophy of the limb, a lived discoloration of the fingers, and detachment of the nails, and amputation was performed. (*Pathol. Chir.* p. 85, 4to. Paris, 1831.) Hence Dupuytren, Breschet, and Malgaigne are of opinion, that the Hunterian method, with a single ligature above the tumor,

should be abandoned. (See *Manuel de Méd. Opér.* p. 195. 12mo. Paris, 1834; *W. Hunter*, in *Med. Obs. and Inq.* vol. v.; *Scarpa on Aneurism*, p. 433, ed. 2; also *Guattani*, *De Cubiti flexuræ aneurysmatibus*, in *Lauth's Coll. Scriptorum*, &c.; *P. Adelmann*, *Tract. Anat. Chir. de Aneurismate spurio varicoso*. Wirceb. 1824; *Dupuytren*, *Répert. Gén. d'Anat. et de Physiologie*, &c. t. viii. p. 104. 1829, and *Clin.* t. i. p. 275, &c.; *Larrey*, in *Mém. de Chir. Mil.* t. iv., and in *Clin. Chir.* t. iii.; *G. Breschet*, *De l'Aneurysme par Transfusion*, in *Mém. Chir. sur Différentes Espèces d'Aneurysmes*, 4to. Paris, 1834.)

ANEURISM BY ANASTOMOSIS

Is the term which Mr. John Bell applied to a species of aneurism, resembling some of the bloody tumors (*nævi materni*) which appear in new-born children, grow to a large size, and ultimately bursting, emit a considerable quantity of blood. Imperfect descriptions of this disease may be traced in writers; though, before the publication of Mr. John Bell's *Principles of Surgery*, it was not classed with aneurisms. Thus, Desault has recorded a case of this affection, for the express purpose of proving that pulsation is an uncertain sign of the existence of an aneurism. (See *Parisian Chir. Journal*, vol. ii. p. 73.)

Aneurism by anastomosis often increases from an appearance like that of a mere speck, or mother's mark, to a formidable disease. The tumor is a congeries of active vessels; and, according to Mr. John Bell, the areolar tissue, through which these vessels are expanded, resembles the gills of a turkey-cock, or the substance of the placenta, spleen, or womb. The irritated and incessant action of the arteries fills the cells with blood, and from these cells it is reabsorbed by the veins. The size of the swelling is increased by exercise, drinking, emotions of the mind, and by all causes which accelerate circulation.

Aneurism by anastomosis is compared by Dupuytren to certain erectile tissues, which naturally appertain to the organisation of the animal body. In this point, there is an agreement between him and John Bell. "A texture of this kind," says Baron Dupuytren, "is met with in the genital organs of many animals of both sexes, and particularly in the urethra, the corpora cavernosa, and the glans penis; on the heads and necks of many birds; on the buttocks of several species of ape; and on parts of the bodies of many other animals. This erectile tissue was regarded by Dupuytren as the model and type of several accidental tissues, which, in consequence of defects of organisation, either original or acquired, may be developed in almost any part of the human body, where they produce tumors, which frequently attain a considerable size. Such growths all exhibit the same vascularity and organisation, the same investment, and the same fibrous interlacement, as the natural erectile tissues do; but their investment is weaker, and the quantity of nerves in them is less. The skin and subcutaneous areolar tissue are particularly often the seats of tumors of this character, which, however, are sometimes met with in almost every part. In particular, they present themselves on the face and the integuments of the cranium; and they form the basis of those congenital marks and swellings, which receive the name of *nævi*. Sometimes they invade the whole of an organ.

Thus, Dupuytren had a case, in which the whole of the external ear and a portion of the contiguous parts were converted into a true erectile mass. In other examples, the new growth leads to the formation of tumors of various size, placed in the very substance, or in the interstices of organs. Under some circumstances, the accidental erectile tissue seemed to Dupuytren to be the product of a degeneration of some natural texture, and of the dilatation of its capillary network; while on other occasions, it appeared to him to be in reality a new organ developed amongst the parts. In the first case, it is confounded on every side with the healthy textures; in the second, it separates these textures from one another, compresses them, and at the same time remains divided from them by a dense investment of areolar tissue, by which it is circumscribed.

The accidental erectile tissues of Dupuytren, corresponding to the aneurism by anastomosis of John Bell, the tetangiectasiæ of Graefe, the cylindroid aneurism of the small arteries of M. Breschet, and the nævi of many writers, are generally of a reddish or brownish colour, often granular on their surface, and situated in the skin, the subcutaneous areolar tissue, or between the muscles. From the investigations of M. Breschet and Scarpa, it appears that the small vessels of the bones, as well as the soft parts, are occasionally the seat of aneurism by anastomosis. (See *Breschet in Répert. d'Anat. &c.* t. i. année 1826; *Scarpa, Annali, Univ. di Med.* 1830. Tumors of this character are either flat or prominent. Sometimes the skin, under which they lie, is scarcely altered. A kind of motion is perceptible in them, synchronous with the arterial pulse. Pressure reduces them to a very small size. Though usually soft, any irritation or excitement renders them remarkably tense and turgid; and if they happen to be wounded, the hemorrhage from them is profuse, and often very difficult to stop. The blood, though of a vermilion colour, and manifestly arterial, does not flow out *per saltum*; but trickles away, just like what happens in cases of fungus hæmatodes. (*Dupuytren, Clin. Chir.* t. iv. p. 8.) Tumors of this description do not spontaneously disappear, but, on the contrary, have a tendency to increase in magnitude. In a few instances, however, they have been known to disperse in consequence of an accidental attack of inflammation; and Professor Gibson, of the United States, gives an instance of this, which occurred during a fever. (*Pract. and Inst. of Surgery.*) Like the natural erectile tissues, these tumors undergo, at the same epochs, and from the same causes, a marked development, and alternations of tension and relaxation, which are, in relation to the healthy or unhealthy state, the strength or weakness of the individual. (See *Dupuytren, Clinique Chir.* t. iv. p. 3—5.)

I have mentioned the observation of Dupuytren, that the accidental erectile tissue forms the basis of those congenital marks and substances, which go under the name of nævi materni. As Mr. Guthrie remarks, however, "It is only when these spots, or marks, are subcutaneous, that their nature approaches to that of aneurism by anastomosis. The milder kinds of subcutaneous disease, to which the name of nævi is often applied, differ much both in appearance and size; sometimes remaining stationary through life, and in others, even disappearing altogether, or becoming small solid

prominences. A nævus is usually of a red colour, with a bluish cast, shining through the skin, which appears to be exceedingly thin. It has also a tolerably defined and terminating edge; and the disease of the vessels seems to be confined to the part discoloured, or extends to a very short distance around it. The tumor, or nævus, although large and elevated in size, does not pulsate. An aneurism by anastomosis, in its most formidable shape, is a swelling of a more or less elevated form. The skin is in general thickened, and its colour is sometimes but little altered, although it more frequently has a bluish cast, which may even tend to red. The pulsatory nature of the tumor is distinct, and the vessels, both arteries and veins, leading to or from it, are enlarged for some distance. The tortuous forms, which the veins particularly assume, give to this disease a distinct character, which cannot be mistaken. (See *Guthrie, On Dis. of Arteries*, p. 341; also *Breschet, Mém. Chir.* p. 28.)

Several writers describe an essential difference between simple nævi and aneurism by anastomosis to be this: in the former, the veins are chiefly affected; in the latter, the arteries. To this view Mr. Guthrie inclines, for he says, "When the arteries partake most of the disease, the indistinct throbbing attendant on it is soon perceptible, and becomes in a short time a marked pulsation; but in cases which more frequently occur in children, and are congenital, and the disease seems more to affect the veins, the swelling will be considerable, the veins greatly dilated, and the part have a varicose appearance, without any pulsatory motion." (See *Guthrie, On Dis. of Arteries*, p. 344.) The *cylindroid aneurism* in the vessels of the smallest diameter, for instance, in the capillaries, says M. Breschet, is named *aneurism by arterial anastomosis*, and *aneurism by venous anastomosis*. In the first of these tumors, there are pulsations synchronous with the pulse, and alternate rises and falls corresponding to the diastole and systole of the arteries, circumstances not remarked in aneurisms of the second kind; which, however, in certain states of the circulation, exhibit a sort of erection or turgescence, produced by the influx of a greater quantity of venous blood. (See *Breschet, in Mém. Chir. sur Différentes Espèces d'Aneurysmes.*)

It is observed by Mr. Syme, that most surgeons have followed John Bell in believing aneurism by anastomosis to consist of a morbid cellular structure, through which the blood passes in its course from the arteries into the veins. However, he has long been one of those who maintain that the apparent cells are really sections of enlarged vessels. (See *Ed. Med. Journ.* No. 98, p. 72.)

In the dissection of a pulsating tumor of the scalp in a patient who had died after the operation of tying the carotid artery, Dr. Maclachlan found the branches of this vessel on the head "degenerated into dilated tubes of extreme thinness and transparency; which, apparently yielding to the impetus of the blood, had become elongated, contorted, and ultimately convoluted on themselves, so as to form, by this species of doubling, the tumors, which constituted this singular disease." They felt like placenta, and the larger portion, immediately over the ear, looked precisely like a bundle of earthworms coiled together. (See *Glasgow Medical Journ.* vol. i. p. 85.) Two cases

are given by Pelletan, fully confirming the view taken of the nature of the disease by Dr. Mac-lachlan and Mr. Syme. (See *Clinique Chir.* t. ii.) Boyer, who saw one of these cases, describes all the arteries of the swelling as being dilated, tortuous, knotty; and though very large in some places, in others contracted. (*Traité des Mal. Chir.* t. ii. p. 295.) In the tumor described by Dr. Mac-lachlan, none of the cells spoken of by Mr. John Bell were found; no parenchyma, as in the spleen; the bulk of the tumor was formed almost entirely by convoluted dilated arterial trunks, the veins being but little changed from their healthy state. He adds, that these arteries did not appear to communicate more freely than by their ordinary inosculation. Some of these conclusions appear to me to require corroboration by a careful anatomical injection of the vessels.

Why, however, should there not be varieties in this disease? The observations of Baron Dupuytren make allusion to modifications of it; and, according to Mr. Guthrie, dissection has shown, that in some instances the tumor has been formed by contortions and reflections of the vessels alone; whilst, in others, the spongelike appearance has been more distinct. (*On Dis. of Arteries*, p. 343.) He adds that in nævi of large size and marked characters, as well as in aneurism by anastomosis, the disease essentially consists of vessels, with the interposition of very little cellular structure. However this may be, I believe Dupuytren correct in describing aneurism by anastomosis as essentially a new growth, consisting of an adventitious erectile areolar tissue, pervaded by a congeries of blood vessels. Thus, in giving the particulars of a case of aneurism by anastomosis of the ear and side of the head, Dupuytren states, that two very different elements were distinguishable in the mass, both by the finger and the eye. The first presented itself in the form of wide, sinuous, irregular knotty tubes, full and compressible, winding over the temple and ear, to which they communicated a knobby appearance. These tubes arose one from another, in the manner of arteries; and the trunk of them, which was equal in size to the little finger, gradually diminished, still retaining, however, in its smallest branches, the diameter of a crow-quill; and these could be traced even into the skin. The origin, the situation, the direction, and the divisions of these tubes, and especially their pulsations, synchronous with those of the heart, and the force of which seemed to threaten every instant a rupture of the tumor, and a perilous hemorrhage, were a sufficient proof that they were formed by the arterial system of the ear, temple, and occipital region, extraordinarily dilated in its trunks, branches, and cutaneous ramifications. All that did not immediately belong to the dilatation of the arterial trunks, was formed of accidental erectile tissue, which filled up the interstices of the network of vessels, and gave to the parts their purple colour, their higher temperature, and their double movement of expansion and subsidence. The tumor shrivelled and became pale under slight compression; but soon resumed its usual colour, size, and tension. (See *Dupuytren, Clin. Chir.* t. iv. p. 13.)

In the female subject, the hemorrhage from the aneurism by anastomosis is sometimes a substitute for menstruation, as the following example illustrates:—Ann Vachot, of St. Maury, in Bresse, was born with a tumor on her chin, of the size

and shape of a small strawberry, without pain, heat, or discoloration of the skin. As it produced no uneasiness, nor inconvenience whatever, it excited little attention, particularly as it did not seem to increase with the growth of the child. For the first fifteen years, there was but little alteration; but, about the menstrual period, it increased suddenly to double the size, and became more elongated in its form. A quantity of red blood was observed to ooze from its extremity. This flux became, in some measure, periodical, and sometimes was sufficiently abundant to produce an alarming degree of weakness. Each period of its return was preceded by a violent pain in the head and numbness. Before and after the appearance of these symptoms there was no alteration in the size of the tumor; the only difference was a small enlargement of the cutaneous veins, with an increase of heat in the part, occasioning some degree of tenderness. The menses at length took place, but in small quantity, and at irregular periods, without influencing the blood discharged from the tumor, or the frequency of the evacuation. The breasts were not enlarged till a late period, nor did the approach of puberty seem to have its accustomed influence on those glands, &c. (See *Parisian Chir. Journ.* vol. ii. p. 73, 74.)

In the article NÆVUS, I shall explain the modes of treatment applicable to the superficial kinds, and at present consider what should be done for the cure or relief of the subcutaneous and deeper forms of the disease, to which the term aneurism by anastomosis more particularly refers.

The first plan which I shall notice is that of removing the disease with a knife. This should only be attempted where the morbid tissue does not extend too deeply, and where there is a fair prospect of being able to take every particle of it away without endangering life by hemorrhage. As Mr. John Bell inculcates, the rule in this operation is not to cut into the diseased part, but to cut it out (see *Principles of Surgery*, Disc. ix.); a piece of advice repeated by Mr. Wardrop, when he says, the surgeon should avoid cutting into the tumor; for, unless this caution be attended to, the hemorrhage is violent; whereas, by making the incisions beyond the diseased structure, the flow of blood is much more moderate. (*Med. Chir. Trans.* vol. ix. p. 212). If the incisions be carried into the morbid tissue, the hemorrhage will be great, because the enlarged and diseased vessels have lost their power of contracting, and there will also be a probability of the return of the disease. "If the nævus be large, round, or of a figure which does not admit of its being removed by two elliptical incisions, so as to give a reasonable hope of union, or if the cicatrix is likely to be large and unseemly, the operation by ligature is to be preferred." (See *Guthrie, On Dis. of Arteries*, p. 346.) I find that extirpation with the knife answers remarkably well when the disease is on the lip, or part of the ear, care being taken to cut in the sound part. I have removed many swellings of this kind from the lips of young children, and always found the hemorrhage cease directly the edges of the wound were brought together with the twisted suture.

The following case, recorded by Mr. Wardrop, affords a valuable illustration of the nature and structure of one form of this disease. A child was born with a subcutaneous nævus on the back part of the neck, of the form and size of half an or-

dinary orange. The tumor had been daily increasing; and when Mr. Wardrop saw it, ten days after birth, the skin had given way, and a profuse hemorrhage had taken place. The swelling was so soft and compressible, that when squeezed in the hand it yielded like a sponge, and was reducible to one third of its original size. On removing the pressure, however, the tumor rapidly filled again, and the skin resumed its purple colour. "Conceiving the immediate extirpation of the tumor the only chance of saving the infant (says Mr. Wardrop), I removed it as expeditiously as possible, and made the incision of the integuments beyond the boundary of the tumor; aware of the danger of hemorrhage where such tumours are cut into. So profuse, however, was the bleeding, that, though the whole mass was easily removed by a few incisions, the child expired.

"The tumor having been injected, by throwing coloured size into a few of the larger vessels, its intimate structure could be accurately examined. Several of the vessels, which, from the thinness of their coats, appeared to be veins, were of a large size, and there was one sufficiently big to admit a full-sized bougie." This vessel was quite as large as the carotid artery of an infant. The boundaries of the tumor appeared distinct, some healthy cellular membrane, traversed by the blood vessels, surrounding it. On tracing these vessels to the diseased mass, they penetrated into a spongy structure, composed of numerous cells and canals, of a variety of forms and sizes, all of which were filled with the injection, and communicated directly with the ramifications of the vessels. These cells and canals had a smooth and polished surface, and in some parts, resembled very much the cavities of the heart, fibres crossing them in various directions, like the chordæ tendineæ. The opening in the skin, through which the blood had escaped during life, communicated directly with one of the large cells, into which the largest vessel also passed. (*Wardrop, in Med. Chir. Trans. vol. ix. p. 203.*)

This case furnishes an instructive warning to us not to attempt to cut out an aneurism by anastomosis, where the size of it, and the age or weakness of the individual, render it probable that he will not bear the loss of blood. I lately saw a child with Messrs. Gilchrist, of Sunbury, aged about two years, with a tumor over the base of the scapula, the nature of which seemed obscure. I made an exploratory puncture in it, meaning to remove it at once, if composed of fat. But the profuse gush of blood which followed the lancet, and the pulsations felt in the swelling during the child's agitation, left no doubt about the case being an aneurism by anastomosis. As the tumor was as large as half an orange, and the child so young, I refrained from the attempt to cut it away, fearful that the bleeding might be more profuse than the little patient would bear. Mr. Lawrence, who has since been consulted, does not recommend the operation.

In the Section on Carotid Aneurisms, I have mentioned the cases, in which Mr. Travers and Mr. Dalrymple cured aneurisms by anastomosis in the orbit, by tying the common carotid artery; a practice which has been repeated with success very lately by Mr. Busk, surgeon to the Dreadnought hospital ship at Deptford. (*See Lond. Med. Gaz. Feb. 27, 1836.*) Professor Pattison

cured an immense anastomosing aneurism of the cheek and side of the face by taking up the carotid artery. (*See Med. and Phys. Journ. vol. xlviii. July, 1822.*) These facts prove, that aneurism by anastomosis, like many other diseases, sometimes admits of being cured, on the principle of cutting off, or lessening, the supply of blood to the part affected.

However, surgeons must not be too confident of being always able to cure the disease, by tying the main artery, from which the swelling receives its supply of blood; and the great cause of failure is the impossibility of preventing in some situations the transmission of a considerable quantity of blood into the tumor, through the anastomosing vessels. A case is recorded by Maunoir, in which he applied a ligature for three days to the carotid artery, and obliterated it; yet the benefit effected seemed to be only temporary, as, in a short time, the tumor was as large as before. (*See Med. and Phys. Journ. vol. xlviii.*) In fact, every vessel, artery, and vein, around the disease, seems to be enlarged and turgid; and the inosculation is so infinite, that no point of the circumference of the swelling can be imagined which is free from them. Etienne Dumand was born with two small red marks on the antihelix of the right ear. Until the age of twelve years, the chief inconveniences were a sensation of itching about the part, occasional bleeding from it, and the greater size of this than of the other ear. The disease now extended itself over the whole antihelix, and to the helix and concha; and the upper part of the ear became twice as large as natural. Slight alternate dilatations and contractions began to be perceptible in the tumor, which was of a violet colour, and covered by very thin skin. Soon afterwards any accidental motion of the patient's hat was sufficient to excite copious hemorrhages, which were difficult to suppress, and, at the same time that they produced great weakness, caused a temporary diminution of the tumor and its pulsations. At length the disease began to raise up the scalp for the distance of an inch around the meatus auditorius, and the hemorrhages to be more frequent and alarming. Pressure was applied to the temporal, auricular, and occipital arteries; but, as the patient could not endure it, the first two of these vessels were tied, the only benefit from which was a slight diminution in the pulsation and bulk of the swelling. This treatment did not prevent the return of hemorrhage, and therefore forty-three days after the first operation, a ligature was applied to the occipital artery. As the disease still continued to make progress, the patient entered the Hôtel Dieu, where on the 8th of April, 1818, Dupuytren tried what effect tying the trunk of the carotid artery would produce on the swelling. As soon as the ligature had been applied, the throbbings ceased, and the tumor underwent a considerable diminution. On the eighteenth day, slight expansions and contractions of the diseased part of the ear were again perceptible, though the swelling had diminished one third, and no throbbing could be distinguished in the neighbouring arteries. The ear was now kept compressed between two masses of charpie. On the forty-sixth day Dupuytren tried what benefit would result from pressing the blood out of the tumor, and then covering it with plaster of Paris. This, however, soon cracked in various places, and could not be kept on the

part. An instrument was then contrived for the reception and compression of the ear. This had the effect of restraining the enlargement of the ear, but was found inadequate to destroy the erectile tissue, which still continued, notwithstanding the pulsation of the arteries had ceased. To have got rid of this portion of the disease, observes Dupuytren, it would have been necessary either to remove the tissue composing it, or to change its organisation. The first plan, on account of the extent of the disease, he did not consider safe; nor could he alter the nature of the disease.

The history of the foregoing case, resumed fifteen years after the operation, proves that though tying the carotid artery is less efficacious in curing a tumor composed of erectile tissue, than a common aneurism, yet it checks its progress, and diminishes its danger. After the carotid artery had been tied in the preceding case, the tumor made little or no progress; the size of the ear remained stationary; and no return of hemorrhages took place. But whatever may be the degree of benefit resulting from the plan of tying the principal artery leading to the disease, Dupuytren gives it as his decided opinion, that it ought to be resorted to when an erectile tumor has invaded a part where compression, cauterisation, and extirpation with the knife, are all impracticable. If there be no carcinomatous tissue blended with the erectile, the progress of the disease will, at all events, be retarded by the operation. (See *Dupuytren, Clinique Chir.* t. iv. p. 5—26; and *Breschet's Trans. of Hodgson's Treatise*, t. ii. p. 296.) The experiment has been made of tying both carotids where the ligature of one proved insufficient to prevent the return of pulsation in the arteries immediately supplying the tumor. Dr. Mussey, of New Hampshire, in America, was consulted in September, 1829, by J. Patee, aged 20, for a large pulsating purple tumor, situated upon the vertex of the head, with a base of about five inches in diameter, and rising about two inches above the cranium. The tumor, which had existed from infancy, had greatly increased during the three years anterior to the above date. Upon its apex was an ulcer, from which hemorrhages had occasionally taken place, and once to the amount of two quarts. "The left temporal artery and vein in front of the ear, seemed through the integuments five eighths of an inch in diameter, and the pulsations of the artery were visible at the distance of fifteen feet. A vein, passing from the tumor down the forehead, was half an inch in diameter; and when the head had been shaved more than twenty pulsating arteries were seen running to the tumor, none of which were under the size of a goose-quill. Dr. Mussey, on the 20th of September, tied the left common carotid; and finding this effectual, he applied a ligature to the right one, twelve days after the first operation. The tumor was covered with a compress moistened with alum-water, and gentle pressure maintained with a bandage. In about three weeks from the period of the second operation, the swelling was not above one third of its original size. Five or six days later, it began very slightly to enlarge again; its colour became deeper; and a feeble thrill was sometimes perceptible in the left temporal artery. As Dr. Mussey found that the ligature of the carotid promised no further benefit, he determined to encircle the tumor by incisions, and to dissect it away rapidly from the pericranium.

More than an hour was occupied in carrying the knife around the base of the tumor; for only an inch and a half of the scalp was cut at a time, and as soon as this was done, firm compression was made upon each lip of the incision, while the vessels were secured with ligatures, more than forty of which were applied in proceeding round the tumor. Notwithstanding these precautions, nearly two quarts of blood were lost. The patient was faint, and continued very feeble for several hours. The naked pericranium, in extent about twenty-five square inches, granulated favourably, and the part healed up. (See *American Journ. of Med. Sciences for Feb.* 1830.)

This case is instructive, as proving still more convincingly than perhaps any other case on record, that tying the carotid artery will not completely cure an aneurism by anastomosis on the head, though the plan has generally succeeded for swellings of this description in the orbit. The ligature, even of both carotids, in Dr. Mussey's case, did not prevent the return of pulsation in the temporal artery; and this unpromising circumstance led him to adopt, without delay, the plan of encircling this disease by a succession of short incisions, in the way practised by Dr. Gibson. Time was not afforded to see whether the growth of the tumor would have been permanently checked, and the return of hemorrhages prevented by the ligature of both carotids, as happened in Dupuytren's case from the ligature of one of them. An interesting question here is, whether the ligature of the carotids made the final excision of the tumor safer, with respect to hemorrhage? Without this preliminary measure, Dr. Gibson, we find accomplished what Dr. Mussey did with it.

Some aneurisms by anastomosis, on or near the surface of the body, may be extirpated with a ligature. A needle, armed with a double ligature, is passed under the erectile tissue. As it is of importance that the ligature go more deeply than the deepest part of the swelling, the assistant ought to raise up the tumor from the subjacent parts, while the needle is pushed under its base. The needle having been cut off, one portion of the ligature is firmly tied over one half of the circumference of the swelling, and the remaining part of it over the other half. Thus the supply of blood to the swelling is completely cut off. After a few days, the diseased mass and the ligatures are detached by an ulcerative process; and, as Mr. Guthrie observes, if the disease has been completely removed, the ulcer heals without difficulty, and the scar is often less than if the operation had been done with the knife. If the disease should not be completely removed, a second ligature may be applied, or, as I have sometimes preferred, the remains of the disease may be extirpated with caustic and pressure. We are informed that this method has been followed, for many years, by the surgeons of the Westminster Hospital. Mr. Keate has made an improvement in it, which consists in employing pins, which, by being passed across, but underneath the tumor, admit of compression being made around a larger surface than could otherwise be included in the ligature. (See *Guthrie, On Dis. of Art.* p. 346.) In one case thus treated by Sir Benjamin Brodie, where the size of the swelling, which was on the forehead, was too extensive to be embraced with a needle and double ligature in the common way, he used straight pins, like

those for the hare-lip, which, being pushed under the disease at right angles, enabled him to pass a ligature around the base of it. In this instance it became necessary to employ a second set of pins and a second ligature; but the cure was ultimately complete. (See *Brodie, in Med. Chir. Trans.* vol. xv. p. 177.)

An infant, six weeks old, was brought to Mr. Wardrop, on account of an aneurism by anastomosis (a subcutaneous nævus) of a very unusual size, situated on the left cheek. The base of the tumor extended from the temple to beyond the angle of the jaw, completely enveloping the cartilage of the ear. At its upper part, there was an ulcer, about three inches in diameter, presenting a sloughing appearance. The tumor was soft and doughy; its size could be much diminished by pressure; there was a throbbing in it, and a strong pulsation in the adjacent vessels. The disease was daily increasing, and several profuse hemorrhages had taken place from the ulcerated part. Mr. Wardrop knowing, from the case to which I have already adverted, the danger of attempting to extirpate so large a tumor of this nature, was led to try what benefit might be obtained by tying the carotid artery. A few hours after this operation, the tumor became soft and pliable; its purple colour disappeared, and the tortuous veins collapsed. On the second day, the skin had resumed its natural pale colour, and the ulceration continued to extend. On the third, the tumor still diminished. On the fourth, the swelling had considerably increased again; the integuments covering it had become livid, and the veins turgid. The inosculating branches of the temporal and occipital arteries had become greatly enlarged. A small quantity of blood had oozed from the ulcer. After remaining without much alteration, the tumor on the seventh day had again evidently diminished. On the ninth, the ulceration was extending itself slowly, and the tumor was lessened fully one half. On the twelfth, the child's health was materially improving. The auricular portion of the swelling had now so much diminished, that the cartilage of the ear had fallen into its natural situation. After poultices had been applied for two days, the central portion of the swelling, which appeared like a mass of hardened blood, was softened, and Mr. Wardrop removed considerable portions of it. On the thirteenth, the child became very ill, and died the following day, exhausted by the irritation of an ulcer, which had involved the whole surface of an enormous tumor. Mr. Wardrop thinks the advantages likely to occur from the plan of tying the main arteries supplying tumors of this nature with blood are, the diminution of the size of the disease; the lessening of the danger of hemorrhage, if the ulcerative process has commenced; and the rendering it practicable to remove the swelling with the knife, though the operation may previously have been dangerous, or impracticable. (See *Med. Chir. Trans.* vol. ix. p. 206—214, &c.)

In the foregoing part of this article, I mentioned the trial of the method of securing the principal branches of the external carotid distributed to the tumor. This plan has generally failed, and it did so in the example under Dupuytren, who, therefore, decided to take up the common carotid itself. Dr. Gibson, in his *Institutes of Surgery*, however, relates a case, in which the practice

succeeded. The patient, a woman, had a large pulsating tumor, which covered almost the whole of the right side of the head, and often bled profusely. Dr. Gibson began with cutting off the supply of blood to the tumor through the occipital and temporal arteries. The swelling now lessened, and its pulsations became weaker; but, as this amendment was only temporary, he proceeded to divide the parts situated between the former incisions, and to tie the vessels. The first cut was two inches in length, and a great deal of blood was lost before all the vessels were secured. The second cut was three inches in extent; but so much blood was now lost, that it became necessary to postpone the completion of the operation. After twelve days, the incisions were extended again; and, at the end of the fortnight, the circumvection of the wound was completed, and the tumor removed: the periosteum being left, from which granulations soon arose, and, in a few weeks, the wound was healed.

Aneurism by anastomosis, when situated on the fingers, may render amputation of them indispensable, provided the whole of the disease cannot be got rid of by other means. I once saw, with Mr. Lawrence, an aneurism by anastomosis, situated on the ring finger of the right hand, in a young woman, about twenty years of age. The disease was attended with painful sensations, extending to various parts of the limb and the breast, and the arm was disqualified for any kind of exertion. In January, 1815, Mr. Hodgson had taken up the radial and ulnar arteries, and the first consequences of the operation were an entire cessation of beating, collapse of the swelling, and relief from pain; but these symptoms all recurred in a few days. Finding compression unavailing, and the sufferings of the patient increasing, Mr. Lawrence proposed amputation of the finger at the metacarpal joint; but as this suggestion was not approved of, he recommended the patient to try the effects of a division of all the soft parts, by a circular incision close to the palm, so as to cut off the supply of blood. This operation Mr. Lawrence performed, in the presence of Mr. George Young and myself, in as complete a manner as can possibly be conceived. All the soft parts, excepting the flexor tendons, with their thecæ and the extensor tendon, were divided. The digital artery, which had pulsated so evidently in the palm of the hand, was fully equal in size to the radial, or ulnar of an adult, and was the principal nutrient vessel of the disease. After tying this and the opposite one, we were surprised at finding so strong a jet of arterial blood from the other orifices of these two vessels, as to render ligatures necessary. I can here only add, that the whole finger beyond the cut swelled very considerably; the incision healed slowly; the swelling subsided, but did not entirely disappear; the integuments recovered their natural colour; the pulsation and pain were removed; and the patient so far recovered the use of her arm, that she could work at her needle for an hour together, and use the arm for most purposes. (See *Wardrop's Obs. on one Species of Nævus*, in *Med. Chir. Trans.* vol. ix. p. 216.)

Mr. Russell, an army surgeon, has published some interesting particulars of an aneurism by anastomosis of the hand. The patient (a laundress), aged 41, had two tumors, each about the size of a walnut; one at the extremity of the

ring finger, the other on that of the little finger of the left hand. They extended along each finger to the middle of it, and were of a violet colour, spongy feel, and of a structure resembling placenta. They shrunk under pressure, but recovered their size on its being removed; throbbed strongly, as did all the vessels of the arm: were excessively painful, and attended with irritability of the whole frame. The radial and ulnar arteries were enlarged, the latter tortuous; and the basilic vein had a varicous appearance. The disease had existed five years, and bled freely and frequently. Mr. Russell recommended the removal of the two fingers at the metacarpal joints, which the woman objected to. In about two months, however, she returned, willing to undergo any operation which Mr. Russell deemed necessary. The disease had now extended itself, so as to form one aneurismal tumor at the commissure of the two fingers. The placenta-like appearance reached to the wrist; the arm was of an erythematous hue to the elbow; the tumors had ulcerated and sloughed; and the carious phalanges protruded from the gangrenous fingers, which were enlarged, and dreadfully painful. The increased pulsation and magnitude of the arteries extended to the axilla. Mr. Russell first tied the ulnar artery, and then amputated the ring and middle fingers, with their metacarpal bones, at the carpus. The stump healed well; and a valuable portion of the hand was saved. Three years after the operation, the vessels of the arm had resumed their natural appearance, and the woman was able to follow the business of a laundress. This case Mr. Russell believes unusual, as having occurred in a person of advanced life; and he considers that it exemplifies the truth of Mr. Wardrop's observation, that a ligature on the artery, leading to the disease, may render the excision of it practicable, when this proceeding would otherwise be unsafe. However, Mr. Russell took up the ulnar artery, he says, for a different purpose; namely, that of enabling him to cut close to the disease. The case proves also, that the secondary effects on the surrounding parts, and, especially, the extensive enlargement of the blood-vessels, will subside after the excision of the erectile tumor. (See *J. Russell*, in *Lond. Med. Gaz.* for *April*, 1836.)

Most of those aneurisms by anastomosis which admit of being extirpated by a ligature, may also be destroyed with strong caustic, like pure potassa, the acid nitrate of mercury, &c. This plan, which was particularly recommended by Mr. Wardrop, and is an old practice, was sometimes adopted by Dupuytren. I have followed it in some instances, and found it answer, though the necessity of repeating the application several times makes it a more tedious method of cure than the ligature. I lately attended a child with Mr. Jephson, of Hampton, for a large thick nævus on the forearm: in this instance, the caustic answered exceedingly well, but it was indispensable to apply it several times. It seems to act partly by converting portions of the tumor into sloughs, and partly by exciting an ulcerative process in the remainder. Dupuytren regarded the actual cautery as a still surer means of extirpating erectile tumors than caustic, though rarely employed, on account of the terror which it excites. (*Clin. Chir.* t. iv. p. 33.) The acid nitrate of mercury was the caustic which he was in the habit of using. (*Op. cit.* p. 28.)

Whatever will change the texture by exciting a general and severe inflammation of an erectile tumor, and an obliteration or annihilation of its vessels, will effect a cure. The treatment on this principle is sometimes practicable. Thus, swellings composed of erectile tissue have occasionally been cured by compression; a plan which Abernethy wrote in favour of, and which both he and Dupuytren tried in several instances with success. The latter sometimes applied this method to the lips, the diseased portion of which was placed between a compressing instrument.

On the principle of changing the organisation of the erectile tissue, and converting it into the fibrous, M. Lallemand has treated certain tumors of this description very successfully by exciting inflammation in them by the introduction of pins through them. One of his most interesting cases is that of an infant three months old, which had an erectile tumor over the scapula, three inches in length and two in diameter, with a red granular surface. Compression had been tried in vain. M. Lallemand first introduced a dozen fine pins through the inferior portion of the tumor, and covered the spaces between them with waxed thread variously twisted. Three days afterwards, a similar operation was repeated on the opposite side. The pins were left in their places seven or eight days, till they had excited sufficient inflammation. The rest of the tumor was afterwards attacked, and in the course of two months and a half, after 120 pins had been introduced at successive periods, a cure was effected, without the loss of a spoonful of blood, a uniform glossy cicatrix being left. Long fine pins, such as are used for transfixing insects, are preferable to common sewing needles. (See *Lallemand*, in *Archives Gén. de Méd.* t. viii. sér. 2.) On the same principle of exciting inflammation, and changing the texture of erectile tumors, cures have occasionally been accomplished by passing a couching needle into them and breaking up their structure. Stimulating injections have likewise been thrown into their substance with the same view. (*Lloyd*, in *Med. Gaz.* for 1836-37.) Most of these latter methods seem to me only eligible when the tumor is of limited size, and its base not too deep.

Erectile tumors are more frequently noticed on the lips than any other part of the body, a circumstance ascribed by Dupuytren to their spongy vascular structure. (*Clin. Chir.* t. iv. p. 51.) But they have been met with in the arm, forearm, hand, fingers, thigh, instep, scalp, ear, cheek, labia pudendi, substance of the skin, muscles, periosteum, bones, kidney, liver, &c. In the work last cited, reference is made to an example where the skin, muscles, and bones of the upper extremity, all became affected from the fingers to the shoulder (t. iv. p. 52).

Besides the varieties of aneurism particularly treated of in the foregoing columns, there is another rarer form of the disease, named by Breschet *cirsoid aneurism* (from *κίρσος*, a varicose vein, and *είδος*, like); and by Dupuytren, *arterial varix*, in consequence of its resemblance to a varicose vein. It consists in the dilatation of an artery in a greater or lesser portion of its extent, and frequently through the whole of an arterial trunk and its branches. In addition to the transverse dilatation, the artery is elongated and tortuous, so as to describe bendings and windings in various degrees.

Independently of these dilatations of the whole arterial tube, nodosities, or small circumscribed aneurismal tumors, present themselves, which are true sacciform aneurisms, and occasionally mixed ones. Most commonly the coats of the vessel are thinned and softened, and, when divided, collapse like those of varicose veins. As Breschet observes, an artery affected in this manner, may easily be mistaken for a varicose vein. The disease has been noticed in the iliac, carotid, brachial, femoral, and tibial arteries, and also in some of less size; such as the occipital, the auricular, radial, ulnar, palmar, plantar, and ophthalmic. This kind of arterial disease, according to Breschet, accompanies an aneurismal varix of long standing. The arterial varix, like the venous aneurismal varix, has been suspected to be attended with some communication between the two orders of vessels, and the passage of a certain quantity of venous blood into the dilated varicose artery. But pathologists have not yet been acquainted with the disease long enough to know its nature perfectly. Some interesting examples of it, illustrated by engravings, are recorded by Breschet. (See *Mém. Chir.* &c.)

ANKYLOSIS, [from ἀγκύλη, a thong or band, or ἀγκύλος, crooked, a term used to describe the condition of an articulation, which either no longer permits the free exercise of all its movements, or is attended with complete immobility. The first Greek derivation sufficiently well illustrates the nature of the uniting medium between the ends of the bones in the most common form of ankylosis; whilst the second, as M. Cloquet observes, has no doubt been chosen, from the fact that ankylosed limbs are generally found in a state of permanent flexion; a position chosen by the patient as the most easy, being that in which the ligaments are least extended, and the synovial surfaces least compressed during the severity of the joint affection, which usually precedes ankylosis. *True* or *complete* ankylosis signifies the fixed and motionless state of a joint, resulting from any of the conditions hereinafter explained.] *False* or *incomplete* ankylosis denotes the impairment of motion, or very considerable rigidity, in an orbicular, or ginglymoid joint, occasioned by adhesions of one synovial surface to the other, or by a thickening of the soft parts on the outside of the joint. [Perhaps it would be better to adopt the definition of M. Houel, who confines the term *ankylosis* to the completely immovable cases, while the others are grouped together under the term "*articular rigidity*."] By Mr. Mayo, ankylosis is divided into *osseous*, *cartilaginous*, and *mixed*, according as the articular surfaces happen to be united through the medium of bone, of cartilage, or of both these substances together. (See *Outlines of Human Pathology*, p. 72.) Of course, this last classification is not intended to comprise some of the varieties of false ankylosis. True ankylosis, then, may be said to denote the complete loss of motion, either in the kind of joint termed *diarthrosis*, where the ends of the bones are tipped with cartilage, and furnished with a capsular ligament, or in the other less moveable sort of joint, termed *synarthrosis*, where the bones are united by an intervening layer of fibro-cartilage, and the articulation is strengthened externally by ligamentous bands. The latter kind of joint can hardly be said to be susceptible of false ankylosis; for it naturally has only a very slight degree of motion, which requires a true ankylosis for its interruption.

Ankylosis is more common in the ginglymoid articulations than others; though sometimes met with in every description of joint. In general, only one joint is ankylosed in the same individual; but sometimes several articulations are the seat of ankylosis, and rare instances are recorded, in which every joint in the body was in this state. Thus, Bernard Conner describes an example of a general ankylosis of all the bones of the human body. (*De stupendo Ossium Coalitu*.) The particulars of a child, twenty-three months old, afflicted with universal ankylosis, are given in *L'Hist. de l'Acad. des Sciences*, an. 1716. In old age, ankylosis in certain parts of the skeleton is a natural change; and in this period of life, it is common to

find the heads of the ribs ankylosed to the bodies of the vertebræ, or the tubercles to the transverse processes, the vertebræ to one another, the ensiform cartilage to the sternum, &c.

Ankylosis, strictly speaking, is not a disease itself, but only an effect or consequence of other affections, and it may follow all those which destroy any one of the conditions, without which the motion of a joint is necessarily interrupted either permanently or for a very considerable time. The author of the article *Ankylosis*, in the *Encyclopédie Méthodique*, refers to a preparation, in which the femur is so ankylosed with the tibia and patella, that both the compact and spongy substances of these bones appear to be common to all of them, without any line of separation being discernible between them; [and the pathological museums of the present day afford many specimens of the kind]. Eustachius, Columbo, and Cruveilhier, have each seen an ankylosis of the lower jaw. Cruveilhier has given the particulars of an ankylosis of one of the articulations of the lower jaw in a very old woman. It commenced in her childhood, from a blow on the side of the face. From the engraving of the parts, it appears that the condyle and glenoid cavity were completely consolidated and united by osseous matter.

Referring to ankylosis in general, we may observe with M. Sanson, that its causes are numerous; inasmuch as every circumstance capable of impairing the articular surfaces, stopping the synovial secretion, lessening the suppleness of the ligaments, or of the soft parts around the joint, or of interfering with the action of the muscles, or the play of the tendons, may hinder the articular surfaces, more or less, from moving upon one another. One thing, almost essential to the production of ankylosis, is the part being kept motionless; and, as M. Sanson well observes, this condition has such influence, that it will of itself bring on the changes which terminate in a joint becoming incapable of resuming its functions, in consequence of true or false ankylosis. An illustration of this fact is afforded by what happens to the Indian Fakirs, who, by way of religious penance, sometimes condemn themselves to continue motionless in certain attitudes for several years, and whose limbs at the expiration of the term are ankylosed in the posture in which they happen to have been so long maintained. The same fact is exemplified in persons who have met with fractures of their limbs; for, in consequence of the motionless state in which the part is kept to promote union of the broken bones, the synovial secretion is diminished, and the fibrous capsules and ligaments of the joint all acquire a rigidity, in which the surrounding cellular tissue participates. The sheaths of the tendons are also no longer duly lubricated. All these circumstances make opposition to the free action of the muscles, which, being themselves weakened by protracted inactivity, are incapable of overcoming the resistance to the motion of the joint. [The paralytic also afford cases of complete ankylosis, with entire disappearance, in rare instances, of all trace of the former joint, and that without appreciable symptoms of inflammation. On the same principle of a long-continued motionless state of an articulation, ankylosis may be induced as a complication and sequel of the contracted state,—or lesion of some particular muscle, or tendon, or the growth of various tumors near the joint,—ex-

ostosis, aneurism, &c.] The contraction of cicatrices after burns, or after a destruction of the soft parts by gangrene or ulceration; and an unyielding state of the cellular tissue and fascia, the effect of extensive and inveterate abscesses in it; and especially inflammation of the synovial membrane, whether acute, or chronic, idiopathic, scrofulous, gouty, or rheumatic, &c., or accidentally excited by mechanical injury of the joints; are all so many circumstances capable of leading to ankylosis. Particular fractures of the joints, or such as are situated near them, if not skilfully treated, are apt to be followed by inflammation of the synovial membrane, absorption of the cartilages, and complete ankylosis. No doubt, in some of these instances, the connection amounts at first only to what authors understand by false ankylosis; but, in the course of time, this becomes converted into complete, or true, characterised by osseous consolidation. On the whole, however, as M. Sanson has remarked, false ankylosis is far more common than the true form of it.

When a bone is fractured near a joint, and this is kept too long motionless, ankylosis is apt to follow. Here the risk is increased by the synovial membrane being likely to inflame; and, indeed, sometimes the accident brings on ulceration of the cartilages. In University College Hospital, I lately saw a case, where the olecranon had been broken across its base, and the detached piece had become completely consolidated to the humerus; yet the patient had considerable power of extending the fore-arm. It is partly in consequence of the risk of inflammation of the synovial membrane and of ankylosis, that fractures of or very near joints are more serious than others differently placed. Wounds and contusions of joints may bring on such changes as terminate in ankylosis. I have already mentioned, that Cruveilhier has seen an instance of ankylosis of the right articulation of the lower jaw. The patient lived to a very advanced age, and, notwithstanding the ankylosis, was able to speak very well, and to masticate by pressing the food with her tongue against the hard substance covering the alveolar processes, where the teeth were deficient. (See *Cruveilhier, Anat. Pathologique*, livr. ix. pl. 5, figs. 1 & 2.)

[Although this work is essentially devoted to practical surgery, some explanation, however brief, will necessarily be expected of the pathological condition of the joints in true and false ankylosis. Without entering into more precise narration of the various kinds of ankylosis, for which the reader is referred to Cruveilhier, Houel, Nelaton, &c., it may be stated generally that true and false ankylosis may be the result of,—1st. Complete fusion or consolidation of the ends of the bones forming the articulation, a condition brought about by the absorption or destruction of the articular cartilages (for the various exciting causes see above), and the reciprocal throwing out of granulations from the exposed ends of the bones thus brought into contact. More or less of atrophic deformity usually attends this complete fusion of the spongy tissue of two bones;—2nd. The formation of a bony sheath or capsule to the joint, or, more commonly, the formation of osseous growths, bridges or stalactites, passing from one bone to the other. Such growths are usually, but by no means invariably, found in the direction of the fibrous tissues, tendons, or ligaments, which surround the joint affected. In a

preparation deposited in the Musée Dupuytren, ankylosis of the elbow is produced by ossification of the brachialis anticus muscle, and in another, the hip-joint is fixed by ossification of the psoas muscle. Gouty concretions deposited around joints may also lead to a similar result; in all these circumstances, however, the articular cartilages and fibro-cartilages remain persistent;—3rd. The cartilages being removed, and the ends of the bones becoming united by fibrous bands in a manner similar to the false union of fractured bones by the same tissue. Such a mode of ankylosis is said to follow the suppuration of joints particularly; and such fibrous tissue has never been known to undergo ossification (Houel);—4th. The formation of fibrous bands within the joint, as the result of synovitis, attended with more or less deformity and absorption of the articular cartilages;—5th. The arrest of the secretion of synovia, and the different alterations of the tissues around the joints, which take place under the various causes quoted above, and which comprise thickening and rigidity of the ligaments and all the fibrous textures, the muscles becoming shorter, paler, degenerated from fatty deposit, the skin contracting remarkably, the nerves even undergoing shortening, while the blood-vessels become tortuous to a corresponding degree. The effect of the pathological conditions comprised under the first and second heads will necessarily be true ankylosis of the joint implicated, while that of the three other groups will be to render the joint more or less completely immoveable; that is, to induce a state of true or false ankylosis, just as the tissues are more or less dense and rigid. Partial dislocation may also attend any of these conditions. As a guide to treatment, it is important that the surgeon decide whether the case before him be one of true or false ankylosis. The task is not an easy one. Chloroform is of course a valuable aid; but an examination should first be made without it; for if the patient experience much pain under attempts to move the joint, the surgeon will thus be supplied with one of the best evidences that he has to deal with a false ankylosis: if the joint admit of the least motion (unless there be evidence of external bony deposit around the joint), most surgeons are agreed that the case is to be regarded as one of false ankylosis. Care must be taken to fix the bone above the affected joint, either by the aid of an assistant, or, as in the case of scapula and pelvis, by mechanical contrivances. The persistence, or diminution of the rigidity and contraction in the muscles and tendons around the joint, under the subsequent action of chloroform, will of course aid the diagnosis, immobility alone being no sign of true ankylosis. But if the patient, when conscious, and with his attention drawn to or diverted from the joint, permit of free manipulation without pain or flinching, and no motion be obtained, the operator may confidently conclude that the case is one of true ankylosis.]

With regard both to true and false ankylosis, the surgeon may generally render more efficient service in preventing than in endeavouring to cure them. In wounds, contusions, and fractures of or near joints, the best means of prevention consist in the rigorous adoption of antiphlogistic treatment at first, and in a later stage in having timely recourse to passive motion of the joint; and then to combine with this plan friction with camphorated and other liniments. When the bones are carious, as in scro-

fulous disease of the vertebræ, and in advanced stages of ulceration of the cartilages of the knee, elbow, wrist, &c., the surgeon, instead of endeavouring to prevent ankylosis, should promote its occurrence, as the most favourable result which the case now admits of. In fact, the completion of ankylosis will denote the termination of the disease. One important indication, however, under such circumstances, is to try to let the limb be ankylosed in the posture which will allow it to be of the greatest possible use. Thus, when the elbow is likely to be the seat of ankylosis, the forearm should be kept bent; but when the knee is concerned, the leg should be kept extended; and when the hip, the thigh should be maintained in a similar position. If ankylosis should have taken place to a certain extent, with the limb in a disadvantageous posture, this may often be still very much improved by the application of splints, and other mechanical contrivances. The action of any mechanical apparatus, however, must be at first moderate, though unremitting. Perseverance will here succeed when violence would fail, by bringing on excessive pain and a dangerous degree of inflammation. Indeed, where the attempts to remove a false ankylosis by gentle passive motion, embrocations, and the cautious use of mechanical means, fail, it is better not to employ violence, because such an ankylosis is preferable to inflammation, abscesses, and ulceration of the joint.

As for true ankylosis, where a complete osseous consolidation has taken place, it may be set down, not only as incurable, but as admitting of no improvement or alteration in the position of the limb, and, whatever that may be, the patient must be content with it. Hence, where there is risk of ankylosis, the great importance of placing the limb in good time in the position which will let it be of the greatest service to the patient.

[Here followed, in former editions of this Dictionary, an account of Dr. Rhea Barton's operation on the hip-joint for the cure of ankylosis, by sawing through the femur between the great trochanter and the neck of the bone, for further particulars of which the reader is referred to the last edition, or to the original in the North American Med. and Surg. Journ. for April, 1827, the nature of the present work not admitting of so long a reference to a single case. It may be added, that the opinion of eminent surgeons of the present day seems to confirm that expressed by Cooper, Sanson, and Cloquet, that such an operation is unjustifiable, and that a true ankylosis is to be regarded as incurable, if so startling a word can with propriety be applied to so happy a result of a grave and formidable disease. The only exception I can conceive to this proposition would be, perhaps, in the case of the lower jaw. It is right perhaps to add, that cases are on record of the successful removal of a wedge-shaped piece of bone from the front of the knee-joint, when ankylosed at an inconvenient angle. (See also, *Joints, Excision of.*)

But when all symptoms of local inflammation are subdued, and the general health is good, much may be effected for the cure of ankylosis, even when a serious amount of partial dislocation is present; and this statement applies particularly to the knee-joint. Many cases of false ankylosis admit of rupture of the impediments to the free motion of the joint by the hands of the surgeon unaided, and the operation is unattended by any

unpleasant consequences; others may be restored to free and natural motion by the careful application of continued mechanical extension. Louvrier broke down all forms of ankylosis by the aid of a powerful piece of mechanism, but with most sad and terrible results. Scarcely less serious were the consequences of the proceedings of Dieffenbach, Palasciano of Naples, and Langenbeck, who practised tenotomy and the division of muscles and fasciæ in addition to the forcible rupture of the impediments to motion in ankylosed joints. The reader is referred for a good historical account of this point of surgery, to M. Bonnet's work, and to Mr. Brodhurst's papers. The latter gentleman has been very successful in his treatment of these cases, of thirty-two of which he gives the statistics. Mr. Brodhurst lays down the following rules as absolutely necessary to success:—The punctures required for the division of the tendons, cicatrices, fasciæ, &c. to be allowed to heal before extension be made, the limb being kept meanwhile at perfect rest, and in its old position: after six or eight days, the impediments to be broken down by alternate motions of flexion and extension of the joint, under chloroform: the limb to be then carefully placed at its former angle in an extending splint contrived for the purpose: after a few days, extension to be commenced, and when completed to be followed up by passive motion of the joint, at first under chloroform. Additional mechanism is applied to the extending splint in cases of partial dislocation. The reader is referred to M. Bonnet's valuable work for descriptions of admirably conceived mechanical instruments.] *Spencer Smith.*

ANTHRAX (ἀνθραξ, a burning coal). See CARBUNCLE.

ANTIMONY. Antimonial medicines are prescribed in a great number of surgical cases, and I may say very commonly in all, where it is desirable to promote the secretions in general, and those of the skin and bowels in particular. Hence, in

the treatment of phlegmonous and erysipelatous inflammation, antimony, especially the potassio-tartrate, or tartarised antimony, is a valuable medicine. In this work, there is no occasion to notice the usefulness of tartarised antimony as an emetic. In inflammations of the brain and its membranes, the eye, the testicles, and the synovial tissues, surgeons frequently prescribe it with great advantage to the patient. Rasori, an Italian physician, used to order it in very large doses, as a means of keeping down inflammation of important organs; and the success of this treatment, as compared with that resulting from the free employment of the lancet, excited a great deal of attention. The disturbance of the stomach, which was at first severe, afterwards generally subsided, and that organ seemed to bear the medicine well. In this country, the tartarised antimony is sometimes employed in cases of dislocation, where the muscles make powerful resistance to the reduction: here it is prescribed in doses of half a grain, repeated every five or ten minutes, until a good deal of nausea is excited, or the patient actually vomits. In this state the patient becomes exceedingly faint, and the muscles no longer oppose the efforts of the surgeon to reduce the dislocated bone. [Now, however, that we possess in chloroform so much more effectual an agent for producing muscular relaxation, the use of antimony in dislocations is almost entirely superseded.] (See DISLOCATION.) In doses of one sixth or one fourth of a grain, joined with calomel and opium, tartarised antimony operates as a diaphoretic, and this combination is useful in various cases of inflammation, which are within the province of surgery.

Tartarised antimony, in the proportion of ʒj. to ʒj. of lard, makes what is called the antimonial ointment, which, where it is desirable to keep up counter-irritation on the surface of the body, is rubbed upon the part in the quantity of about a drachm, and for a few minutes at a time. The effect is to bring out pustules, and even ulceration, the degrees of which, and their influence on the complaint, are to determine how often and long the antimonial frictions are to be continued. In some cases, these excite pustules and ulceration in distant parts; a fact deserving to be particularly remembered.

[The pulvis antimonii comp. (Ph. Lond.) and the patent preparation known as Dr. James's powder, are both composed, according to the analysis of Mr. Phillips, of antimoniate of antimony (antimonious acid) and phosphate of lime. Serious doubts have been entertained about the efficacy of both these preparations, and according to Mr. Phillips, the high state of oxidation of the antimony which they contain will fully account for their inactivity. (See *Transl. of Lond. Pharmacop.* 1851, p. 270.)] Dr. Elliotson prescribed the pulvis antim. comp. in doses of 100 grains, and it seemed to have no effect. In general, says Dr. A. T. Thomson, it displays no influence whatever on the system. Its occasional activity may be ascribed to the oxide being accidentally in the state of a protoxide. (See *Thomson's Elem. of Mat. Med.* p. 923, ed. 2.) A like uncertainty has also been found to attend the use of Dr. James's powder. (See *Pereira's Mat. Med.* ed. 3, vol. i. p. 680.) Hence, when antimonials are indicated in surgery, for the purpose of promoting the secretions generally, and of the skin in particular, it is best to prescribe the potassio-tartrate of antimony, which

is of known and uniform activity. This may be combined with calomel or opium, or both, according to the indications of the case; or it may be given in aqueous solution, or in the form of vinum antim. potass. tart. (P. L.) A quarter of a grain of the salt is contained in each fluid drachm of the latter preparation.

The precipitated sulphuret of antimony is only prescribed as an ingredient in the compound calomel pill.

The muriate of antimony, termed butter of antimony, from its consistence, is a powerful caustic, more frequently employed by foreign than British surgeons, who, in consequence of its deliquescent character, consider it an inconvenient application.

ANTRUM, *Diseases of.* The diseases to which the antrum, or maxillary sinus, is liable, commence either in its mucous lining, the bony laminae of which it is composed, or the fangs of the teeth, which form projections at the lower part of it. Sometimes the mucous membrane inflames, and, becoming thickened, closes the natural opening by which the antrum communicates with the nasal fossae, and the consequence is an accumulation of mucus or limpid fluid in it. On other occasions a purulent fluid is secreted; or a fluid is formed, which concretes into small masses, and has the characters of adipocire. The antrum may also be the seat of polypi, sarcomatous tumors of various descriptions, erictile tumors, or aneurism by anastomosis, and scirrhus swellings. Then its bony parietes may be softened, more or less absorbed, or carious, or affected with necrosis or exostosis. (See *Gensoul, Sur quelques Maladies Graves du Sinus Maxillaire*, &c. p. 2, 8vo. Paris, 1833.) Sometimes extraneous bodies, detached portions of bone, a bullet, and even insects, may lodge in the antrum, and cause, for many years, very afflicting pains.

COLLECTION OF MUCUS.

In general, the disease, which is not very common, takes place unpreceded by any causes which are at all manifest. It is alleged mostly to happen in young subjects: of three patients seen by Boyer, the eldest was not more than twenty. (*Traité des Mal. Chir.* t. vi. p. 139.) Sir Benjamin Brodie has seen only two cases: one patient was a lady, whose age is not specified; the other, a boy. A collection of transparent fluid in the antrum is undoubtedly a much rarer occurrence than one of pus. (See *Brodie, in London Med. Gaz. for Dec.* 1834.) As Mr. Hunter has noticed, whether the obliteration of the outlet, leading to the nose, be a cause or only an effect of the disease, is not easily determined; but from some of the symptoms, there is great reason to suppose it an attendant. "If it be a cause, we may suppose that the natural mucus of this cavity, accumulating, irritates, and produces inflammation for its own exit, in the same manner as an obstruction to the passage of the tears through the ductus ad nasum produces an abscess of the lachrymal sac." (See *Hunter's Natural Hist. of the Teeth*, p. 174, ed 3.) A most interesting example of the effects of the lodgement of mucus in the antrum, is that recorded by Dubois: a boy, between seven and eight years of age, was observed to have at the base of the ascending nasal process of the upper jaw-bone, on the left side, a small, very hard tumor, of the size of a nut. As it caused no pain, and did not increase,

his parents gave themselves no concern about it. When he was about sixteen, however, the swelling began to increase, and to be somewhat painful. Before he was eighteen, its augmentation was so considerable, that the floor of the orbit was raised up by it; the eye thrust upwards, and nearly closed; the arch of the palate pushed down in the form of a tumor; and the nostril almost effaced. Below the orbit, the cheek made a considerable prominence; while the nose was thrown towards the opposite side of the face, and the skin at the upper part of the tumor, below the lower eyelid, was of a purple red colour, and threatening to burst. The upper lip was drawn upwards, and behind it; all the gums of the left side were observed to project much further than those on the opposite side of the face; and, at this point alone, the thinness of the bony parietes of the antrum was perceptible. The patient spoke and breathed with great difficulty; he slept uneasily, and his mastication was painful. The case was at first supposed by Dubois, Sabatier, Pelletan, and Boyer, to be a fungus of the antrum, and an operation was considered advisable. In proceeding to this measure, the first thing, which attracted the notice of Dubois, was a sort of fluctuation in the situation of the gum, behind the upper lip; a circumstance which led him to give up the idea of the case being a fungus, though he expected that, on making an opening, merely a small quantity of ichorous matter would escape, affording no kind of information. In this place, however, he determined to make an incision along the alveolar process, whereby a large quantity of a glutinous substance like lymph, or what is found in cases of ranula, was discharged. A probe was now introduced, with which Dubois could feel a cavity equal in extent to the fore part of the tumor; and in moving the instrument about, with the view of learning whether any fungus was present, it struck against a hard substance, which felt like one of the incisor teeth, near the opening that had been made. Five days after this first operation, Dubois extracted two incisors and one grinder, and then removed the corresponding part of the alveolar process. As the hemorrhage was profuse, the wound was now filled with dressings, which in two days came away, and enabled Dubois to see with facility all the interior of the cavity. At its upper part, he perceived a white speck, which he supposed was pus; but, on touching it with a probe, it turned out to be a tooth, which was then extracted, in doing which some force was requisite. The rest of the treatment merely consisted in injecting lotions into the cavity, and applying common dressings. In about six weeks, all the hollow disappeared; but the swelling of the cheek and palate, and the displacement of the nose, still continued. In the course of another year and a half, however, every vestige of deformity was entirely removed. (*Dubois, Bulletin de la Faculté de Méd. an 13, No. 8.*)

In the case of the lady attended by Sir Benjamin Brodie, there was no distinct fluctuation, but a kind of crackling sensation communicated to the fingers, like what would be felt in pressing upon very thin horn, or parchment. (*Med. Gaz. loc. cit.*)

With respect to the treatment of collections of mucus, or transparent albuminous fluid, in the antrum, by means of injections thrown into that

cavity through the natural opening in it, while the head is inclined to the opposite side, for the purpose of facilitating the escape of the collected fluid, as proposed by Jourdain in 1765 (*Mém. de l'Acad. de Chir. t. iv. p. 357*), I fully agree with Deschamps and Boyer, that the method is a bad one; because long before the disease forms an outward swelling, we may presume that the natural communication between the antrum and the nostril is closed, and will not readily admit of a tube being introduced into it. Some plan, more fraught with promptitude and efficiency, is here demanded. Hence, the practice of opening the tumor in an eligible place, and to an extent sufficient for the discharge of the mucus, and the prevention of another accumulation, is what all surgeons of the present day recommend. (*Deschamps, Traité des Maladies des Fosses Nasales, et de leur Sinus, p. 231, 8vo. Paris, 1804; Boyer, Traité des Mal. Chir. t. vi. p. 145, 8vo. Paris, 1818.* Indeed, that Jourdain's proposal was attended with too much difficulty for common practice, was the sentence long ago pronounced upon it by a committee of the Royal Academy of Surgery in France. If the case has not destroyed, or softened the front or lower portion of the bony texture of the antrum, and any bad tooth is situated under it, this should be extracted, and a perforation made into the antrum through the bottom of the socket. This aperture may be preserved as long as necessary, by the introduction of a piece of elastic gum catheter, which is to be fastened to the adjacent teeth, and through which the secretion in the antrum may escape, and lotions be injected. (See *Deschamps, Traité des Mal. des Fosses Nasales, &c. p. 234.*) However, as Hunter remarks, if the forepart of the bone has been destroyed, even though the case be merely a collection of mucus, or pus, an opening may be made on the inside of the lip: but, from a fear that there would be difficulty in maintaining such an aperture, he still inclines to the practice of drawing one of the teeth. (*Natural History of the Teeth, p. 176, ed. 3.*)

In general, I believe that the extraction of one of the molar teeth will not prove very applicable to the present case; first, because the thick albuminous fluid requires a larger opening than can be thus obtained; and secondly, because when the surgeon is called upon to perform an operation, the bony texture of the antrum is already very thin, much softened, or even partially absorbed above or behind the alveoli; consequently, as soon as the surgeon has made an incision above the gum, or in the part of the swelling presenting itself on the roof of the mouth, he finds that a probe will immediately enter the antrum. All that he has to do, therefore, is to enlarge this opening with a small pair of bone-pliers, or a strong knife. Mr. Hunter's apprehension about the difficulty of maintaining the opening, and of the likelihood of a return of the accumulation, does not appear to be confirmed by what happened in the cases under Dubois and Sir Benjamin Brodie. The latter informs us, that, "after dissecting the membrane of the cheek from the jaw, I took a curved scalpel, bent laterally, with a strong sharp point, and introduced the point into what seemed the thin bony parietes, or boundary of the tumor. Immediately there escaped a large quantity of transparent fluid, like very thin mucus, something like what we find in cases of ranula. I then introduced a probe into

the cavity of the antrum, and found that it might be passed in any direction. There was neither tumor nor dead bone in it ; and the cavity seemed to be in a natural state, except that it was enormously dilated. I next enlarged the opening, cutting out a circular portion of thin bony shell, formed by the expanded parietes of the antrum. After the operation, the tumor subsided, and, in a few weeks, the cheek was not larger than the other. The aperture made by the scalpel has continued pervious to this day, though it is ten years since I performed the operation. The lady wears a plug, which she takes out night and morning, and with her own hand introduces the point of a syringe, and washes out the antrum." (See *Lond. Med. Gaz. for Dec. 1834.*)

ABSCESSSES OF THE ANTRUM.

Abscesses are far more common than collections of mucus. Violent blows on the cheek, inflammatory affections of the adjacent parts, and especially of the pituitary membrane lining the nostrils, exposure to cold and damp, and, above all things, bad teeth, may bring on suppuration within the antrum. The first symptom is pain, often imagined to be toothache, particularly if there should be a carious tooth in this part of the jaw. Such pain, however, extends more into the nose, than that usually does which arises from a decayed tooth, and affects the eye, orbit, and frontal sinuses. (See *Hunter, On the Teeth*, p. 175, ed. 3.) But these symptoms are insufficient to characterise the disease, the nature of which is not unequivocally evinced till a much later period. Sir Benjamin Brodie adverts to inflammation of the antrum, independent of local causes ; a case more obscure than when some manifest local cause of irritation is present. In one such example, he was led to make a perforation above the second molaris, but no pus escaped. The patient was relieved by taking two grains of calomel and half a grain of extract of opium three times a day till the gums had become rather sore. (*Brodie, in Lond. Med. Gaz. for Dec. 1834.*) An inflammation of the antrum, tending to suppuration, is generally of longer duration than one entirely dependent on a caries of a tooth. There is a constant dull pain in the cheek, with frequent paroxysms of lancinating torture, and a great deal more sympathetic febrile disturbance than attends toothache ; and the violence of the suffering increases more and more, until, at last, a hard tumor is perceptible below the cheek-bone. By degrees the swelling extends over the whole cheek ; but it afterwards rises to a point, and forms a circumscribed hardness, perceptible above the back grinders. This symptom is accompanied with œdema, redness, and sometimes with suppuration of the external parts. In some instances, when there is an outward abscess, the matter has made its way into that situation through the bone, and there is consequently a communication between both collections of matter.

The circumscribed elevation of the tumor, above the molares, does not, however, occur in all cases ; for sometimes the matter makes its way towards the palate, causing the bones of this part to swell, and, at length, bringing them into a state of caries, or necrosis, unless timely assistance be given. In some other cases, the matter escapes between the fangs and sockets of the teeth, and causes a soft prominent swelling in the gums.

Lastly, there are certain examples, in which the matter passes into the nostril of the same side, when the patient is lying with his head on the opposite one. If this mode of evacuation should be frequently repeated, it affords relief, and prevents the tumor both from pointing externally, and bursting, as it would do if the purulent matter could find no other outlet. But this evacuation of pus from the nostril is not so common as might be expected ; for, according to Mr. Hunter, the opening between the antrum and cavity of the nose is generally stopped up. He even seems inclined to think, as I have already observed, that the disease may sometimes be occasioned by the impervious state of this opening, in consequence of which the natural mucus of the antrum collects in such quantity as to irritate and inflame the membrane with which it is in contact, just as an obstruction in the ductus nasalis hinders the passage of the tears into the nose and causes an abscess in the lachrymal sac. This is a point, however, on which even Mr. Hunter would not venture to speak with certainty ; for it is by no means impossible, that the impervious state of the opening is rather an effect than the cause of the disease, since inflammation in the antrum is often manifestly produced by causes of a different kind, and the opening in question is not invariably closed.

Sir Benjamin Brodie concurs with other surgeons in believing that inflammation of the antrum is mostly dependent on local causes, and more commonly upon the irritation of a bad tooth than any other circumstance. This gives rise to inflammation at the bottom of the alveolus. Here matter forms, and not always being able to escape between the fang and the socket, destroys the periosteum lining the latter part, causes absorption of the bone, and the inflammation is propagated to the lining of the antrum. In many instances, the case becomes complicated with dead as well as carious bone. (See *Brodie, in Lond. Med. Gaz. for Dec. 1834.*)

In the early stage of these cases, leeches, fomentations, calomel, opium, and saline purgatives may be employed for the purpose of reducing the inflammation, and preventing its advance to suppuration. But when an abscess has formed, and the matter is confined in the antrum, the indications dictate other treatment. The matter should be discharged, and any source of local irritation which is discoverable removed.

Abscesses in the antrum require a free outlet : and if the surgeon neglects to procure it nature herself ultimately does what is requisite ; but not till the patient's agony has been greatly prolonged, and the disease has extended further than ought to have been allowed. At length, however, the pus makes its appearance, either towards the orbit, the alveoli, the palate, or, as is mostly the case, towards the cheek. The matter having thus made its escape from the antrum, bursts through the soft parts, and the opening becomes fistulous.

In all cases, whether the pus be simply confined in the antrum, or whether the case be conjoined with a necrosis, or caries, the principal indication is to discharge the matter.

The ancients seem to have known very little about the treatment of diseases of the antrum. Drake, an English anatomist, is reputed to be the first proposer of a plan for curing abscesses of this cavity. (*Anthropologia Nova. Londini. 1727.*)

However, Meibomius was much earlier in proposing, with the same intention, the extraction of one or more of the teeth, in order that the purulent matter might escape through the sockets.

Drake and, perhaps before him, Cowper, aware that the fangs of the teeth did not reach completely into the antrum, proposed making a perforation through the socket into that cavity, for the purpose of letting out the matter, and injecting such fluids as were judged proper.

In the treatment of abscesses of the antrum, the extraction of one or more teeth, and the perforation of the alveoli, being generally essential steps, the first question is, what tooth ought to be taken out. In general, caries, or even a mere continual aching of any particular tooth, ought to decide the choice. But if all the teeth should be sound, which is not often the case, writers direct us to tap each of them gently, and to extract that which gives most pain on this being done. When no information can thus be obtained, other circumstances ought to guide us. All the molar teeth, and the second bicuspid, correspond with the antrum. They even sometimes extend into this cavity, the fangs being then only covered by the pituitary membrane; and the bony lamella, which separates the antrum from the alveoli is always very thin towards the back part of the upper jaw. Hence, when the choice is in our power, it is best to extract the first or second molar, as in this situation the alveoli can be more easily perforated. Though, in general, the first bicuspid and canine tooth do not communicate with the antrum, their fangs approach the side of it, and from their sockets an opening may readily be extended into that cavity.

When one or more teeth are carious, they should be removed, because they are both useless and hurtful. The matter frequently makes its escape, as soon as a tooth is extracted, in consequence of the fang having extended into the antrum, or rather in consequence of its bringing away with it a piece of the thin partition between it and the sinus; or the discharge may follow from the partition itself being carious. If the opening thus produced be sufficiently large to allow the matter to escape, the operation is already completed. But as it can easily be enlarged it ought always to be so when there is the least suspicion of its being too small. However, when no pus makes its appearance after a tooth is extracted, the antrum must be opened by introducing a pointed instrument in the direction of the alveoli. For this purpose a trocar, an awl, or a gimlet, may be employed.

Sir Benjamin Brodie prefers an instrument, formed like a common hydrocele trocar, but a little larger, and of course without a cannular. "It should not be made of the best steel; for (says he) I once used a common trocar, made of steel, and it broke while I was performing the operation. In this case, I extracted the broken portion very easily; but such an accident might occur, and great difficulty be experienced in extracting the point of the instrument. When the bottom of the alveolus is broken down, the matter will readily escape from the antrum, and you may introduce a probe and explore the cavity, so as to ascertain whether there be in it any dead bone or not. Sometimes there is a piece of dead bone at the bottom of the alveolus, and then you have only to

wait patiently until an opportunity occurs for its removal. At other times you will feel the dead bone, after the probe has entered the antrum, and the opening already made may not be sufficient for its extraction. Under these last circumstances, the opening must either be enlarged, or another made in a different place." (*Brodie, in Lond. Med. Gaz. for Dec. 1834.*)

For the performance of this operation some recommend that the patient should sit on the ground, in a strong light, resting his head on the surgeon's knee, who is to sit behind him in a chair. Immediately the instrument has reached the cavity, it is to be withdrawn. Its entrance into the antrum is easily known by the cessation of resistance. After the matter is discharged, surgeons advise the opening to be closed with a wooden stopper, in order to prevent the entrance of extraneous substances.

The stopper is to be taken out two or three times a day, to allow the pus to escape. If there be no dead bone present, this plan soon disposes the parts affected to discontinue the suppuration and resume their natural state. The cure may often be accelerated by employing injections of weak brandy and water, lime water, or a solution of the sulphate of zinc. Two or three days after an opening has been made into the antrum, Sir Benjamin Brodie begins to wash out the cavity, one or twice daily, with tepid water, injected by means of a syringe with a slightly curved pipe. The water injected will now generally pass into the nostril, and the cavity can be very completely washed out. If the water does not pass out of the nose, it shows that the natural opening between the two turbinated bones is blocked up. (*Brodie, op. cit.*)

Some surgeons prefer a piece of bougie, or of elastic gum catheter, instead of the wooden stopper. The examples on record where the extraction of a tooth and perforation of the bottom of the antrum were the means of curing abscesses of that cavity are very numerous. (See *Farmer's Select Cases*, No. ix.; *Gooch's Cases*, p. 63, new ed.; *Palsyn, Anatomie, &c.*; *Brodie, op. cit.*)

When the bones are diseased, the simple perforation will not accomplish a cure. A probe will generally detect caries or necrosis. The foetid smell and ichorous appearance of the discharge will also leave little doubt that the bones are diseased.

When there are loose pieces of dead bone or other foreign bodies to be extracted, it may be requisite to make a larger opening in the antrum than can be obtained through the socket of a tooth. Instances also occur where patients have lost all the molar teeth, and the sockets are quite obliterated, so that a perforation from below cannot be effected. Some practitioners object to sacrificing a sound tooth. In these circumstances, a perforation in the antrum may be made above the alveolar processes; as first suggested by Lamorier. The operation consists in making a transverse incision, below the malar process and above the root of the first molar. Thus the gum and periosteum are divided, and the bone exposed. A perforating instrument is to be conveyed into the middle of this incision, and the opening in the antrum made of the requisite size with a small pair of cutting pliers, or other convenient instrument. In this

way an opening can be more conveniently made than with a trephine. The following way of making the opening is recommended by Sir B. Brodie: "Raise up the cheek, so as to expose the membrane covering the gum on the side of the face, and, with a scalpel, make a transverse incision down to the bone. In one case (says he), I did otherwise, thinking the division of the membrane, as a separate part of the operation, was unnecessary; but the consequence was that the blood escaped into the cellular membrane underneath, and there was an immense ecchymosis, rendering the rest of the operation very difficult. Then perforate the thick plate of bone, as nearly as possible to what you suppose to have been the original seat of the disease." The best instrument for this purpose, according to Sir Benjamin Brodie, is a pair of sharp-pointed strong scissors. "Apply them to the bone in their closed state, using them as a chisel, and they will easily penetrate it, and go into the antrum. With these the bone may be broken away to the requisite extent." (See *Mém. de l'Acad. de Chir.* t. iv. p. 351; *Gooch's Obs. Append.* p. 138.) Some examples occur, where it is absolutely necessary to expose a great part of the surface of the bone, and to cut away the dead pieces which are wedged, as it were, in the living ones. In general, however, it is prudent to wait till the dead bone is loose; and, in the meanwhile, to restrict our interference to preventing the lodgment of matter, and maintaining cleanliness.

TUMORS OF THE ANTRUM.

Ruysch, Bordenave, Desault, Abernethy, Weinholt, Gensoul, Liston, Regnoli, Guthrie, and others, have recorded examples of various kinds of tumors affecting the antrum. Surgical writers describe polypi of the antrum; and as growths of the kind have their origin from parts invested by mucous membranes, it is natural to expect that the antrum would occasionally be the situation of them. Yet the disease must here be very rare; and Sir Benjamin Brodie even regards the history and treatment of polypi of the antrum as altogether hypothetical; and he adds, "No polypus, I believe, ever existed in the antrum, around which a surgeon could put a ligature; and I never heard of the operation being performed." (See *Lond. Med. Gaz.* for Dec. 1834, p. 350.) In no hospital, either civil or military, have I had an opportunity of seeing a polypus of the antrum; neither has any case presented itself to me out of an hospital. I join Sir Benjamin Brodie therefore in believing the disease to be exceedingly rare. There are, however, some good authorities in confirmation of the fact that polypi do sometimes grow in the antrum. (*Eichhorn, Chelius, &c.*) Certain other tumors, originating within the antrum, are far more common; some of which are of a fibrous, sarcomatous, or osteo-sarcomatous character, free from malignancy; while the others are of a malignant cancerous kind, partaking of the nature of medullary tumors, or of carcinoma, and sometimes of both of these formidable diseases together.

[Non-malignant tumors in the antrum, while in an incipient state, present but few symptoms. The absence of pain at first, and the indolence of their growth, tend to conceal their existence;] but such a disease rarely exists a long while without being accompanied with some affection of the neighbouring parts; and hence its presence may generally

be ascertained before it has attained such a size as to have altered in a serious degree the natural shape of the antrum. This information may be acquired, by examining whether any of the teeth have become loose, or have spontaneously fallen out; whether the alveolar processes are sound, and whether there are any fungous excrescences making their appearance at the sockets; whether there is any habitual bleeding from one side of the nose, any sarcomatous tumor at the side of the nostril, or towards the great angle of the eye. When the swelling, however, has attained a certain size, the bony parietes of the antrum are dilated, and an extraordinary swelling of the cheek takes place. [It is principally, if not exclusively, in these cases of non-malignant disease that operations for the removal of a portion or the whole of the superior maxilla are now considered admissible.]

A swelling of the parietes of the antrum, in consequence of an abscess, or a sarcomatous tumor in its cavity, may lead us to suppose the case an enlargement of the bones, or an exostosis. The symptoms of the two first affections have been already detailed. One sign of an exostosis, besides the absence of the symptoms characterising an abscess or a tumor in the antrum, is the thickened parietes of this cavity forming a solid resistance; whereas, in cases of mere expansion, the dimensions of the surface of the bone being increased while its substance is rendered proportionally thinner, the tumor is softer and more yielding.

When such an exostosis depends upon a particular constitutional cause, and especially upon one of a venereal nature, it must be attacked by remedies suited to this affection. But when the disease resists internal remedies, and its magnitude is likely to produce an aggravation of the case, a portion of the bone may be removed with a trephine or other cutting instrument.

Malignant tumors of the antrum are attached to the mucous membrane, and fill up the cavity. At first the patient has but little pain, and the existence of the disease is scarcely indicated by any particular symptoms. But as the disease advances, things are different. The tumor, growing larger, presses upon the inner surface of the antrum, and causes its bony parietes to become dilated. By degrees it forms a projection in the cheek. After a time, there is another projection in the bony palate. Then one occurs at the inferior part of the orbit; and there is still another blocking up the nostril. From the pressure of the tumor, the osseous texture of the antrum is absorbed, the alveoli are destroyed, and the teeth are loosened, or drop out. At length the morbid growth either makes its way into the orbit, displacing the eye, and passes through the orbital plate of the frontal bone into the skull, and proves fatal, or else it protrudes through the front, or lower part of the antrum: in either of which last situations it presents a large foetid, bleeding mass, bringing the patient to his doom with equal certainty. In the Museum of University College are three specimens of malignant disease of the antrum; in two, the swelling made its way from the antrum to the brain; in the third, which was taken from an elderly woman, a patient of mine, who died in the hospital, the medullary and scirrhus mass, after entering the orbit, and displacing the eye, caused

ulceration and sloughing in the cheek, and a protrusion of some of the tumor in this direction. The woman, who had suffered indescribable agony from the pressure of the tumor, as it continued to enlarge, was at length worn out by the discharge, irritation, and repeated bleedings from the disease. I remember a boy in St. Bartholomew's Hospital, many years ago, in whom a medullary tumor, beginning in the antrum, made its way through the orbital plate of the frontal bone and cribiform plate of the ethmoid into the cranium. He was only comatose about forty-eight hours before he died, though the portion of the swelling projecting into the cranium, and causing a corresponding depression in the anterior lobes of the brain, was equal in size to a small orange.

Mr. Abernethy published an account of a very singular disease of the antrum. The patient, who was thirty-four years of age when the account was written, perceived, when about ten years old, a small tumor on his left cheek, which gradually attained the size of a walnut, and then remained for some time stationary. About a year afterwards, the tumor having again enlarged, a caustic was applied to the integuments, so as to expose the bone. The actual cautery was next applied, and an opening thus made into the antrum. After the exfoliation, the antrum became filled with a fungus, which rose out upon the cheek, and could not be restrained by any applications. Part of the fungus also made its way into the mouth, through the socket of the second bicuspid tooth, the other teeth remaining natural. The disease continued in this state nine years, occasionally bleeding in an alarming way. When the patient was in his twentieth year, the whole fungus sloughed away during a fever, and never returned. After this, the sides of the aperture in the bone began to grow outwards, forming an exostosis, which rapidly attained a great magnitude. A small exostosis took place in the mouth, but became no larger than a horsebean. The exostosis of the maxillary bone was of an irregular figure, and projected from the whole circumference of the aperture a great way directly forward. Mr. Abernethy compared its appearance, when he was writing, with that of a large tea-cup fastened upon the face, the bottom of which may be supposed to communicate with the antrum. The diameter of the cup, formed by the circular edge of the bone, was three inches and a half; the depth two inches and seven eighths. The general height of the sides of the exostosis, from the basis of the face, was two inches; its walls were not thick, and terminated in a thin, cellular edge. The integuments, as they approached this edge, became thinner, and they extended over it into the cavity. The exostosis now reached to the nose in front, and to the masseter muscle behind; above it included the very ridge of the orbit, and below it grew from the edge of the alveolar process. A line that would have separated the diseased from the sound bone would have included the orbit and nose, and indeed one half of the face. Mr. Abernethy saw no means of affording the man relief. (*Trans. of a Society for the Improvement of Med. and Chir. Knowledge*, vol. ii.) See also a case related by Harrison. (*New Lond. Med. Journ.* vol. i. p. 1.)

In a case of fungus, which had distended the antrum, hindered the tears from passing down into the nose, raised the lower part of the orbit, caused

a protrusion of the eye, made two of the molar teeth fall out, and occasioned a carious opening in the front of the antrum, through which opening a piece of the fungus projected, Desault operated as follows:—The cheek was first detached from the os maxillare, by dividing the internal membrane of the mouth at the place where it is reflected over this bone. Thus the outer surface of the bone was denuded of all the soft parts. A sharp perforating instrument was applied to the middle of this surface, and an opening made more forward than the one already existing. The plate of bone situated between the two apertures was removed with a little falciform knife, which, being directed from behind forward, made the division without difficulty. The opening thus obtained being insufficient, Desault endeavoured to enlarge it below, by sacrificing the alveolar process. This he endeavoured to accomplish with the same instrument; but finding the resistance too great, he had recourse to a gouge and mallet. A considerable piece of the alveolar arch was thus detached, without any previous extraction of the corresponding teeth, three of which were removed by the same stroke. In this manner an opening was procured in the external and inferior part of the antrum, large enough to admit a walnut. Through this aperture a considerable part of the tumor was cut away with a knife curved sideways, and fixed in its handle. A most profuse hemorrhage took place, but Desault, unalarmed, held a compress in the antrum for a short time; this being removed, the actual cautery was repeatedly applied to the rest of the fungus, and the cavity was filled with charpie dipped in powdered colophony.

On the eighteenth day, the swelling was evidently diminished, the eye less prominent, and the epiphora less visible. But, at this period, a portion of fungus made its appearance again. This was almost entirely destroyed by two applications of the actual cautery. It appeared again, however, on the twenty-fifth day, and required a third and last recourse to the cautery. From this time the progress of the cure went on rapidly. Instead of fungous excrescences, healthy granulations were now formed in the bottom of the sinus. The parietes of the antrum gradually approaching each other, the large opening, made in the operation, was reduced to a small aperture, hardly capable of admitting a probe. Even this little opening closed in the fourth month, at which time no vestiges of the disease remained, except the loss of teeth, and a very obvious depression just where they were situated. (*Œuvres Chir. de Desault, par Bichat*, t. ii.; and *Parisian Chir. Journ.* vols. i. and ii.) See other cases recorded by Acoluthus (*Act. Cur. Natur.*); Garengot (*Mém de l'Acad. de Chir.*; Dupuytren (*Bulletins de la Faculté de Méd.*); Gensoul (*Sur quelques Mal. du Sinus Maxil.* p. 9); Béclard (*Gensoul*, op. cit. p. 11); Georgi (*Gensoul*, op. et loc. cit.); Velpeau (*Ib.* p. 14); Anderson (*Glasgow Med. Journ.* vol. ii. p. 74); Canolles (*Recueil Périodique de la Soc. de Méd.* t. ii. No. 9); Eichorn (*Diss. de Polypis in Antro Highmori*, Goett. 1814); Sandifort (*Museum Anat.* vol. ii. tab. 30); Leveillé (*Recueil de la Soc. &c.* t. i. p. 24); Weinhold (*Von den Krankheiten der Geischtsknochen*, p. 27, 4to. Halle, 1818.)

In some of these examples, a cure is stated to have been accomplished; in others, the disease returned, and proved fatal. The question then

arises, whether all the tumors were malignant, or only a part of them? Those which were permanently cured might have been of a different nature, not partaking of the character of medullary sarcoma, nor of that of carcinoma.

With respect to Desault's operation, and any other performed for a medullary, or cancerous tumor of the antrum, it would have been desirable to know what was the state of the patient some considerable time after the removal of the swelling; for, as Sir Benjamin Brodie correctly observes, a malignant disease may appear to be cured for a twelvemonth, and yet return. The circumstance of Desault's patient seeming to be well four months after an operation of this kind, by no means proves that it produced a permanent cure. (See *Lond. Med. Gaz. for Dec. 1834*, p. 351.) Dr. Anderson, of Glasgow, has furnished information respecting the case in which he extirpated a fungous tumor from the antrum after it had produced complete absorption of the bone. "This patient died of pectoral inflammation, *five years and a half afterwards*, when she had just recovered from the operation of removing nearly the whole of the *lower jaw*. On a minute examination of the antrum, the former disease was found to have been permanently cured by the operation." (*Anderson, in Lond. Med. Gaz. for Feb. 1835*.) Hence, Dr. Anderson disapproves of leaving a patient, even with such a tumor, to his fate.

Sir Benjamin Brodie formerly attempted to destroy a malignant tumor of the antrum in its early stage. The bone being absorbed, he cut out a large portion of the membrane, which now constituted the only boundary of the antrum. He now came to a considerable tumor, growing from a broad surface. "The outer part of the tumor, which was of soft consistence, I broke down with my fingers, and I then turned the tumor out, so that the antrum appeared to be perfectly empty. But this was not done without an enormous, and, indeed, frightful hemorrhage." Notwithstanding the free use of caustic and the actual cautery, the disease returned and grew faster than it could be destroyed, and proved fatal. Mr. Liston's observations are to the same purpose. The malignant form of the disease, even in a very early stage, is pronounced by him to be unmanageable: "The tumors, if removed, are speedily reproduced, and the fatal termination may be accelerated by interference. I have removed tumors from the antrum maxillare, and from the frontal sinus; but the parts soon became occupied by morbid growths of a more formidable character than the preceding; the membrane and bone appear to assume a disposition to generate such disease; and the fungous protrusions cannot be kept down with escharotics, nor with the actual cautery. The antrum, when filled with such tumors, is easily laid open. The cheek is divided perpendicularly from over the inferior orbital foramen to the mouth, and the soft parts are dissected from off the bone. The cavity may then be exposed by means of a small trephine; but this instrument is scarcely ever required, the parietes being so softened as to yield easily to the knife: though pliers, or cutting forceps, may be useful in enlarging the aperture. By the guidance of the finger, the attachments of the morbid growth are separated with a blunt-pointed bistoury; and a scoop is used to turn out the diseased mass. The root of the tumor is then

touched with a red-hot iron; and by this implement, or by dossils of lint, the hemorrhage is easily arrested. But *such operations*, considering the result of those which have been practised, *are scarcely justifiable*." (See *Liston's Elem.* part. ii. p. 158.)

Mr. Liston delivers the same judgment on the operation of removing a malignant tumor of the antrum, along with its investment, and every part of the bone to which it is connected. "The disease," says he, "is seldom, if ever, seen by the surgeon early enough to admit of any operation being practised with the least chance of ultimate success. At a sufficiently early period, the removal of the bone of the parietes of the cavity containing, and from which the tumor has grown, must, without doubt, afford a better chance, and is, in every point of view, to be preferred to the old operation of what was called trephining the antrum." The view which I now entertain of this subject, in relation to malignant tumors of the antrum, completely agrees with that taken by Sir Benjamin Brodie and Mr. Liston. If a case were needed to confirm the accuracy of their opinions, I would refer to that in which Mr. Guthrie lately operated in the Westminster Hospital, and who has honestly laid the true result of it before the public, as every other surgeon ought to do who ventures to try the practice. (See *Guthrie, in Lond. Med. Gaz. for January 16, 1836*.) The example in which M. Georgi operated, it seems, was followed by a lasting cure; but, as M. Gensoul remarks, there was a double piece of good luck in this instance; viz. that of a necrosis of the bone taking place to a sufficient depth to prevent the return of the disease, and the not less fortunate circumstance of such necrosis being restricted precisely to the half of the face. (See *Gensoul, Sur quelques Mal. Graves du Sinus Maxil.* p. 19.) The case recorded in the *Bulletins de la Faculté de Méd.*, where Baron Dupuytren removed about one third of the alveolar arch and the bony palate, in order to extirpate an osteo-sarcoma, proved successful; but some forms of this disease are not regarded by British pathologists as partaking of the same degree of malignancy, the same unfavourable state of the constitution, and the same disposition to return, as attend medullary sarcoma and a truly cancerous swelling. The operations performed by Acoluthus, of Breslaw, and M. Garengot, of Paris, are reported to have terminated in cures.

M. Gensoul, lately principal surgeon of the Hôtel Dieu at Lyons, instead of merely opening the antrum, cutting away as much of the tumor as possible, and attacking the rest with caustic or the cautery, proposed and practised another operation, founded on the same principles as are recognised by the best surgeons as applicable to every operation for the removal of a cancerous breast. "Here," says he, "all writers agree in advising amputation to be performed at the base of the disease, so as to make all the incisions in the sound parts; and this is exactly what I recommend to be done in diseases of the maxillary sinus." (*Sur quelques Maladies graves du Sinus Maxillaire*, p. 4.) Gensoul's first operation was executed on the 26th of May, 1827. (Op. cit. p. 18.) Mr. Lizars advocated this operation in the year 1826, but had no opportunity of performing it till the month of December, 1827. This subject I shall have occasion to return to in another place, where

a description of the operation of removing the antrum will be given. (See BONES, EXCISION OF.)

As it appears from the foregoing observation, that whatever operation is done, the patient has a fairer prospect of being cured by it when the disease does not partake of a medullary or cancerous nature, and as, likewise, the chances of recovery are so bad in the latter cases that many of the best surgeons pronounce any operation for them unjustifiable; it would be very desirable if the character of the disease could always be determined before the tumor has made its way beyond the limits of the antrum. I remember that Sir Benjamin Brodie once mentioned to me a case in which he was able to ascertain the medullary consistence of the tumor by the introduction of one of his exploratory grooved needles. The plan seems to be one deserving of recollection. In the case here referred to, the antrum was removed by another surgeon, but the disease returned. In a case which was in the University College Hospital, under my care, the disease, which was malignant, had caused ulceration of the cheek, and thrown out a firm fungous bleeding mass in that direction; so that the nature of the case was but too manifest. But if there had been no such protrusion of the disease through the cheek, the projecting part of the tumor in the roof of the mouth admitted of manual examination; and its consistence could be felt to be in some places elastic; in others, firm, like scirrhus, or mammary sarcoma. In fact, the preparation taken from the patient, an aged female, after her death, exemplifies a combination of these two structures; and is placed in the museum of University College. Mr. Mayo, in noticing the importance of discriminating osteo-sarcoma from medullary sarcoma of the antrum remarks,—“The only criterion that I am acquainted with for determining the nature of the swelling is to plunge a lancet into it; when, if the disease is osteo-sarcoma, the peculiar crisp sensation of cutting that texture will be perceived.” (See *Mayo's Outlines of Pathology*, p. 278.)

[In the present day a grooved needle or very small trochar is used to procure a particle of the tumor, in order to have its character tested by microscopical inspection.]

A few years ago, Mr. Pattison suggested the expedient of tying the carotid artery, as likely to bring about the dispersion of fungous diseases of the antrum, without the necessity of meddling with the tumor itself. He adverts to three cases, the results of which, according to his account, were favourable to the practice. (See *Burns, On Anat. of the Head*, &c. ed. by Pattison.) However, the ligature of an arterial trunk has been tried by Sir Astley Cooper, to stop the progress of medullary tumors in other situations, but without success (see *Surg. Essays*); and Mr. Liston declares, that the statement of a malignant tumor in the antrum having been arrested by ligature of the common carotid, is not borne out by facts. (*Elem. of Surgery*, part ii. p. 161.) In M. Magendie's *Journ. de Physiologie* is a case, in which this eminent physician tried in vain to stop the progress of a tumor of the antrum by tying the common carotid artery.

INSECTS IN THE ANTRUM.

It is said, that insects in this cavity may sometimes make it necessary for the surgeon to open it. This case, however, must be exceedingly rare;

and even what we find in authors (*Pallas, De Insectis Viventibus intra viventia*) appears so little authentic, that I should hardly have mentioned the subject if there were not in a work of repute (*Med. Comm.* vol. i.) a fact which appears entitled to attention. Mr. Heysham, a medical practitioner at Carlisle, relates that a strong woman, aged sixty, in the habit of taking a great deal of snuff, was subject, for several years, to acute pains in the antrum, extending over one side of the head. These pains never entirely ceased, but were more severe in winter than summer, and were always subject to frequent periodical exacerbations. The patient had taken several anodyne medicines, and others, without benefit; and had twice undergone a course of mercury, by which her complaints had been increased. All her teeth on the affected side had been drawn. At length, it was determined to open the antrum with a large trocher, though there were no symptoms of an abscess, nor of any other disease in this cavity. For four days no benefit resulted from the operation. Bark injections, and the elixir of aloes, were introduced into the sinus. On the fifth day, a dead insect was extracted, by means of a pair of forceps, from the mouth of the cavity. It was more than an inch long, and thicker than a common quill. The patient now experienced relief for several hours: but the pains afterwards recurred with their former severity; oil was next injected into the antrum, and two other insects, similar to the former, were extracted. No others appeared, and the wound closed. The pains were not completely removed, but considerably diminished for several months, at the end of which time they became worse than ever, particularly affecting the situation of the frontal sinus.

Bordenave has published, in the twelfth and thirteenth volumes of the *Mém. de l'Acad. de Chir.* edit. 12mo., two excellent papers on diseases of the antrum. In the thirteenth volume he relates a case, in which several small whitish worms, together with a piece of foetid fungus, were discharged from the antrum, after an opening had been made on account of an abscess of this cavity, attended with caries. (P. 381.) But, in this instance, the worms had probably been generated after the opening had been made in the cavity; for when they made their appearance, the opening had existed nine months. Deschamps refers to another case, in which M. Fortassin, his colleague at La Charité, found in the antrum of a soldier, whom he was dissecting, a worm of the *ascaris lumbricus* kind, four inches in length. (*Traité des Mal. des Fosses Nasales*, &c. p. 107.) Such an example is also recorded in one of the volume of the *Journ. de Méd.* [The *linguatula tænioides*, the parasite which infests the frontal sinus, and which somewhat resembles the *ascaris lumbricus*, is not unlikely to have been the worm described as found in the antrum in the above cases.] Where cases of this description present themselves in a living subject, it would be advisable to inject oil into the cavity of the antrum, and then endeavour to wash out the extraneous substances, by throwing into the sinus warm water, by means of a syringe.

ANUS. The lower termination of the intestine, named the rectum, is so called, and its office is to form an outlet for the fæces. It is furnished with muscles, which are peculiar to it; viz. the sphincter, a voluntary muscle, which forms its base and support, and keeps it habitually closed, in order that the loathsome affliction of a continual and involuntary discharge of the fæces may not occur; and the *levator ani*, which serves to draw it up into its natural situation, after the expulsion of the fæces. It is also surrounded, as well as the whole of the neighbouring intestine, with muscular fibres, and a very loose sort of cellular substance. In addition to the levator ani, the proper dilating muscle, the sphincter is antagonised by the diaphragm and muscles forming the anterior parietes of the abdomen. The want of something corresponding to a sphincter is a main source of the annoyance resulting from an artificial anus. The external sphincter is covered by skin, which is abundantly furnished with sebaceous follicles; hairs grow upon it, and it is folded on itself to assume the character of a mucous tissue. At the place of its duplicature it is thrown into many diverging wrinkles, which become effaced whenever the anus is dilated. The common cuticle terminates just within the anus, where it is replaced by the kind of epidermis belonging to mucous textures. In the mucous membrane, are distributed the terminal ramifications of the hæmorrhoidal arteries; from which originate a multitude of tortuous plexiform veins, constituting the lowermost radicles of the vena portæ.

[It is important, however, to remark, that the hæmorrhoidal plexus of veins does not terminate exclusively in the portal vein, but empties itself also partly into the internal iliac veins; so that a

communication exists around the termination of the intestine between the *portal* and the *general* venous system. This communication is of great advantage when there is congestion of the liver, or any obstruction to the circulation of the blood through that organ, since it affords the only other channel through which, under such circumstances, the engorged portal system can relieve itself; and this outlet is conveniently provided at the lowest point, where from the weight of the superincumbent column of blood, the congestion is greatest. This provision for relief, however, is often insufficient, and hence, as is well known, hepatic obstructions are very commonly attended by distension and dilatation of the hæmorrhoidal veins.]

The anus receives a large supply of nerves from the sacral nerves and from the hypogastric plexus; and numerous mucous cryptæ lie under the mucous membrane, which their secretion serves at once to lubricate and to protect.

ABSCESSES IN THE NEIGHBOURHOOD OF THE ANUS. — FISTULA IN ANO.

[Abscesses in the neighbourhood of the anus are of very common occurrence; but their especial importance, in a surgical point of view, arises not so much from their frequency, as from the circumstance, that, after the evacuation of the matter, they are rarely found to heal spontaneously, like ordinary abscesses in other situations, but their parietes, after contracting to a certain extent, leave a permanent fistulous channel by the side of the lower part of the bowel. This latter condition, which is an after consequence of the abscess, constitutes the disease commonly known as *fistula in ano*.] Those cases in which the matter has made its escape by one or more openings through the skin only, are called *blind external fistulæ*; those in which the discharge has been made into the cavity of the intestine, without any orifice in the skin, are named *blind internal*; and those which have an opening both through the skin, and into the gut, are called *complete fistulæ*.

Abscesses about the anus, according to Mr. Pott, may present themselves in different forms.

"Sometimes the attack is made with symptoms of high inflammation; with pain, fever, rigor, &c., and the fever ends as soon as the abscess is formed. In this case a part of the buttock, near the anus, is considerably swollen, and has a large circumscribed hardness. In a short time, the middle of this hardness becomes red and inflamed, and in the centre of it matter is formed."

"The pain is sometimes great, the fever high, the tumor large and exquisitely tender; but however disagreeable the appearances may have been, or however high the symptoms may have risen, before suppuration, yet, when that end is fairly and fully accomplished, the patient generally becomes easy and cool; and the matter formed under such circumstances, though it may be plentiful, is good."

"On the other hand, the external parts, after much pain, attended with fever, sickness, &c., are sometimes attacked with considerable inflammation, but without any of that circumscribed hardness which characterises the preceding tumor, instead of which the inflammation is extended largely, and the skin wears an erysipelatous appearance. In this the disease is more superficial, the quantity of matter small, and the cellular membrane sloughy to a considerable extent."

"Sometimes, instead of either of the preceding appearances, a gangrenous suppuration takes place, and the cellular tissue is affected in the same manner as it is in a carbuncle."

"In this case, the skin is of a dusky red or purple colour; and, although harder than in a natural state, it has by no means that degree of tension or resistance which it has either in phlegmon or in erysipelas. The patient has generally at first, a hard, full, jarring pulse, with great thirst and restlessness. If the progress of the disease be not stopped, or the patient relieved by medicine, the pulse soon changes into an unequal, low, faltering one; and the strength and the spirits sink in such a manner as to imply great and immediately impending mischief. The matter formed under the skin, so altered, is small in quantity and bad in quality, and the adipose membrane is gangrenous and sloughy throughout the extent of the discoloration."

"Sometimes the disease makes its first appearance in the induration of the skin, near to the verge of the anus, but without pain or alteration of colour; which hardness gradually softens and suppurates. The matter, when let out in this case, is small in quantity, good in quality; and the sore is superficial, clean, and well-conditioned. On the contrary, it now and then happens, that although the pain is but little, and the inflammation apparently slight, yet the matter is large in quantity bad in quality, extremely offensive, and proceeds from a deep crude hollow."—(*Pott, On Fistula in Ano*, Lond. 1765, p. 7—10.)

Abscesses near the rectum happen with particular frequency in persons who are habitually costive, and, according to Sir Benjamin Brodie, in those also who have been troubled with piles. His observations confirm the truth of some cases on record, where abscesses of the rectum are stated to have been produced by foreign bodies penetrating through the mucous membrane of the bowel and sphincter muscle, into the cellular tissue. "I was sent for (he informs us) to a gentleman, who had a very uneasy feeling in the rectum. I thought he laboured under internal piles, and prescribed for him something, which, however, did not relieve him. The next day, as he was no better, I examined the rectum, and found a hard substance sticking in the mucous membrane: with some difficulty I extracted it, and found it to be part of the core of an apple, which the patient had eaten." If this had not been extracted, no doubt an abscess might have been produced by the side of the gut. Sir Benjamin Brodie was sent for to another patient, who had an abscess near the rectum; and, after he had opened it, he detected a long fish-bone sticking across it, which was extracted. The bone had evidently penetrated the mucous membrane of the bowel; and, in all probability, some faeculent matter had passed by the side of it, so as to account for the remarkable putridity of the matter. (See *Lond. Med. Gaz.* for 1835, 1836, p. 27.) The experience of Sir Benjamin Brodie likewise agrees with the remark made by the greater number of writers on this subject, respecting the occasional formation of abscesses near the rectum in persons otherwise healthy, though they take place far more commonly in unhealthy individuals.

"The place where the abscess points," observed Mr. Pott, "and where the matter, if let alone, would burst its way out, is various and uncertain.

Sometimes it is in the buttock, at a distance from the anus; at other times near its verge, or in the perineum; and this discharge is made sometimes from one orifice only, sometimes from several. In some cases there is not only an opening through the skin, externally, but another through the intestine into its cavity; in others, there is only one orifice, and that either external or internal.

"Sometimes the matter is formed at a considerable distance from the rectum, which is not even laid bare by it; at others, it is laid bare also, and not perforated: it is also sometimes not only denuded, but pierced; and that in more places than one."

"All consideration of preventing suppuration is generally out of the question; and our business, if called at the beginning, must be to moderate the symptoms; to forward the suppuration; when the matter is formed, to let it out; and to treat the sore in such a manner as shall be most likely to produce a speedy and lasting cure."

"When no symptoms require particular attention, and all that we have to do is to assist the maturation of the tumor, a soft poultice is the best application." When the disease was of the phlegmonous kind, Mr. Pott preferred letting the skin become very thin before an opening was made in it; but, at the present day, abscesses near the anus and rectum are commonly opened directly the matter has formed. "This kind of tumor is generally found in people of full sanguine habits: and who, therefore, if the pain be great, and the fever high, will bear evacuation, both by phlebotomy and gentle cathartics."

"When the inflammation is erysipelatous, the quantity of matter formed is small, compared with the size and extent of the tumor; the disease is rather a sloughy, putrid state of the cellular membrane, than a single abscess, and therefore the sooner it is opened the better; if we wait for the matter to point, we shall wait for what will not happen; at least not till after a considerable length of time, during which the disease will extend itself."

"When, instead of either of the preceding appearances, the skin wears a dusky purplish-red colour; has a doughy, unresisting feel, and very little sensibility: when these circumstances are joined with an unequal faltering kind of pulse, irregular shiverings, a great failure of strength and spirits, and inclination to doze, the case is formidable, and the event generally fatal."

"The habit, in these circumstances, is always bad; sometimes from nature, but much more frequently from gluttony and intemperance. What assistance art can lend must be administered speedily; for if the disease be not stopped, the patient will sink. Here is no need for evacuation of any kind; recourse must be immediately had to medical assistance; the part affected should be frequently fomented; a large and deep incision should be made into the diseased part, and the applications made to it should be of the warmest, most antiseptic kind."

"Strangury, dysury, and even total retention of urine, are no very uncommon attendants upon abscesses in the neighbourhood of the rectum and bladder; more especially if the seat of them be near the neck of the latter organ. They sometimes continue from the first attack of the inflammation until the matter is formed, and has made its way outward, and sometimes last a few hours only." (*Pott, op. cit.* p. 11—22.)

If these symptoms are not very urgent, they may commonly be relieved by a gentle cathartic, accompanied by diluent and diuretic medicine, but if they amount to a complete retention, the use of the catheter will occasionally become necessary. This practice, however, was condemned by Pott, who observed that the retention here is spasmodic, and arises from irritation, notwithstanding the participation of the neck of the bladder, in some degree, in the inflammation.

The most effectual means of relief seemed to him to be the warm bath, or semicupium; the application of bladders with hot water to the pubes and perineum; and, above all other remedies, the injection of a glyster, consisting of warm water, oil, and opium. (*Op. cit.* p. 22.)

"A painful tenesmus is no uncommon attendant upon an inflammation of the parts about the rectum. If a dose of rhubarb, joined with the confect. opii, does not remove it, the injection of thin starch and opium, or tinct. thebaic., is almost infallible."

"The bearing down in females, as it proceeds, in this case, from the same cause (*viz.* irritation), admits of relief from the same means as the tenesmus."

"In some habits, an obstinate costiveness attends this kind of inflammation, accompanied, not unfrequently, with a painful distention and enlargement of the hæmorrhoidal vessels, both internally and externally. While a large quantity of hard fæces is detained within the large intestines the whole habit must be disordered; and the symptomatic fever, which necessarily accompanies the formation of matter, must be considerably heightened. And while the vessels surrounding the rectum (which are large and numerous) are distended, all the ills proceeding from pressure, inflammation, and irritation, must be increased." (*p.* 23.) Here we must agree with Pott, that antiphlogistic treatment and a low cool regimen must be the remedies: while laxative glysters and a soft cataplasm applied externally, will serve to relax and mollify the parts, at the same time that it hastens the suppuration.

[In the present day it is the custom to open freely *all* abscesses about the anus immediately the matter is formed and fluctuation can be detected. An early and free incision is the best means of preventing burrowing of the matter, and affords the patient the best chance of the immediate closure of the abscess without the formation of a fistula.]

"In making the opening, the knife or lancet should be passed in deep enough to reach the fluid: and when it is in, the incision should be continued upward and downward, in such manner as to divide all the skin covering the matter. By these means, the contents of the abscess will be discharged at once and future lodgment of matter will be prevented." (*Pott, op. cit.* p. 29.)

[After the matter has been discharged, a piece of soft lint or wool should be lightly inserted between the lips of the incision, to prevent its closing too rapidly; and attention should be paid to the state of the wound from day to day while the cavity of the abscess is contracting, as it is important to maintain a free and depending outlet for the matter which continues to be secreted; but all stuffing and distention of the cavity should be carefully avoided.]

"Upon discharge of the matter, the external

swelling subsides, and the inflamed colour of the skin disappears; the orifice, which at first was sloughy and foul, after a day or two are past becomes clean, and contracts in size; but the discharge, by fretting the parts about, renders the patient still uneasy."

"As this kind of opening seldom proves sufficient for a cure (though it sometimes does), induration, in some degree, remains; and if the orifice happens not to be a depending one, some part of the matter lodges, and is discharged by intervals, or may be pressed out by the fingers of an examiner. The disease, in this state, is not very painful; but it is troublesome, nasty, and offensive: the continual discharge of a thin fluid from it creates heat, and causes excoriation in the parts about; it daubs the linen of the patient, and is at times very fetid: the orifice also sometimes contracts so as not to be sufficient for the discharge; and the lodgment of the matter then occasions fresh disturbance." (*Pott, op. cit.* p. 51.)

The reason of abscesses near the rectum less frequently healing up than others, is referred by Sir B. Brodie to the sinus, or passage for the matter, running through the sphincter muscle. "The sphincter muscle is constantly in motion, contracting and dilating, and consequently there is not the repose which is necessary for the cure of the abscess." (*Op. et vol. cit.* p. 27.) Sir B. Brodie acknowledges that an abscess sometimes forms high up by the side of the rectum, above the sphincter; but this he regards as an occurrence comparatively rare. "These abscesses," he observes, "attain a very large size before the patient suffers much pain or inconvenience. There is at first merely a sense of bearing down of the rectum, occasioned by the pressure of the abscess on it; but as the abscess increases in size, the patient has violent painful spasms, and a constant feeling as if he wanted to pass a motion, while there are no fæces in the bowel. His sufferings are now excessive. You examine the external parts, and you see nothing; you introduce your finger into the rectum, and there you perceive the abscess pressing on one side of the gut, and very much diminishing its diameter. Having thus ascertained the position of the abscess, if you examine the external parts again, although you could discover nothing in the first instance, you will probably be able to detect it, deep seated as it is, at the side of the anus. More resistance will be offered to the pressure of the finger here than elsewhere; and if you introduce two fingers of the left hand into the rectum, and press on the abscess from within, you will make it actually bulge a little externally." Sir B. Brodie then proceeds to explain, that abscesses, formed high up by the side of the rectum, if left to themselves, generally burst into it.

When the intestine is found to be separated from the surrounding parts by the matter, the operation of dividing it should be performed at the time the abscess is first opened, and not be deferred—"For," said Mr. Pott, "if it be done properly, it will add so little to the pain which the patient must feel by opening the abscess, that he will seldom be able to distinguish the one from the other, either with regard to time or sensation; whereas, if it be deferred, he must either be in continual expectation of a second cutting, or feel one at a time when he does not expect it."

"The intention in this operation is to divide the intestine, from the verge of the anus, up as high as the top of the hollow in which the matter was formed; thereby to lay the two cavities of the gut and abscess into one, and by means of an open wound, instead of a hollow or sinuous sore, which serves for the lodgment of matter, to obtain a firm and lasting cure." (*Pott*, op. cit. p. 38.) The operation, however, is effectual partly on another principle, first particularly explained by Sir Benjamin Brodie. The division of the sphincter muscle had indeed been insisted upon by others (see *Chelius*, *Handb. der Chir.* b. i.); but the principle of its utility had not been duly pointed out. "When the abscess is laid open, the fibres between it and the bowel must be divided; and the sphincter muscle being thus set at liberty, not only is there a free and ready escape for the matter, but the action of the muscle, which prevents the healing of the abscess, is put an end to. This then is the mode of curing the abscess: lay it open into the bowel, dividing at the same time the fibres of the sphincter muscle, which lie over it." (*Brodie*.)

When a discharge of the matter by incision is too long delayed or neglected, the abscess makes its own way out, by bursting somewhere near to the fundament, or through the intestine into its cavity; or sometimes in both directions. In either case the discharge is made sometimes by one orifice only, and sometimes by more.

It is seldom that there is more than one orifice communicating with the interior of the bowel, although there may be several openings externally upon the integuments; but commonly these openings are only so many distinct burstings of the skin covering the matter, and all, be they few or many, lead and open immediately into the one single abscess.

Authorities differ as to the mode in which these abscesses originate:—

In 1820, some interesting remarks on this subject were published in France by M. Ribes, deduced from the dissection of not less than seventy-five persons, who had died with fistulæ. The doctrine started by M. Ribes was that a fistula is formed by the bursting of an internal pile into the rectum, and the consequent passage of a portion of the contents of the bowel into the orifice. Now this is not the common mode in which an abscess near the anus is occasioned; yet it sometimes happens as an exception to the common course of things. According to M. Ribes, the orifice is *always* within five or six lines above the junction of the internal membrane of the bowel with the external skin, and may usually be seen if the patient forces the gut gently down, as in going to stool. This account of the common situation of the internal opening, when the abscess communicates with the bowel, agrees with the observations of Sabatier, Larrey, and Chelius. (See *Recherches sur la situation de l'Orifice interne de la Fistule de l'Anus*, &c.; *Quarterly Journ. of Foreign Med.* No. 8, Oct. 1820; *Larrey*, in *Mém. de Chir. Mil.* t. iii. p. 415; *Chelius*, *Handb. der Chir.* b. i. p. 577. 8vo. Heidelb. 1826.)

[Sir B. Brodie believes that "the disease is originally an ulcer of the mucous membrane of the bowel, extending through the muscular tunic into the cellular membrane external to the intestine. It is admitted," he observes, "by every one, that in the greater number of cases of fis-

tulæ in ano, there is an inner opening to the gut, as well as the outer opening; and I am satisfied that the inner opening always exists, because I scarcely ever fail to find it, now that I look for it in the proper place, and seek it carefully. I have, in a dead body, examined the parts where fistulæ had existed, several times, and in every instance I have found an inner opening to it. This affords a very reasonable explanation of the formation of these abscesses; it is almost impossible to understand, on any other ground, why suppuration should take place in the vicinity of the rectum, more than in any other part of the body, and why the cellular membrane there should suppurate more than cellular membrane elsewhere."

Sir B. Brodie thinks that the most common cause of abscess of this kind, is the lodgment of hard fæces in the bowels: by the straining that takes place to expel them, the mucous membrane gets torn or abraded at one part, and then the passage of the fæces causes ulceration. Some time afterwards straining again occurs, and the muscular tunic gives way, and the fæces escape into the cellular texture. He believes the inner orifice is always situated immediately above the sphincter muscle, just the part where the fæces are liable to be stopped, and where an ulcer is most likely to extend through both the tunics. (See *Lancet*, vol. i. 1843—44, p. 530.)

Mr. Syme, on the other hand, affirms positively, that "the mucous membrane always remains entire in the first instance, and is never perforated until after suppuration has taken place." He thinks that, in the first place, a collection of matter is formed between the integuments near the anus and the mucous coat of the rectum, but that "the contents of the abscess by far most frequently escape by an aperture through the external integument. This opening is usually very small, often hardly perceptible; and if the cavity be examined after the contents have been discharged, the mucous membrane will be found completely denuded, to more or less extent, at the distance of an inch, or a little further, from the anus. As the matter, in order to get into this situation, would, if originally deposited externally to the sphincter, have to penetrate between the muscular fibres, its formation probably takes place in connection with the inner coat of the bowel whence it proceeds outwards, overcoming the obstacles opposed to its progress in this direction, instead of pursuing an inward course, in opposition to the general tendency which leads to the external surface of the body."—"If the disease be still permitted to pursue its course unchecked, a small aperture is, sooner or later, formed also through the thin denuded part of the mucous membrane of the rectum. It may seem surprising that this second opening should be formed after the matter has procured vent elsewhere; but there can be no doubt as to the fact; and it agrees completely with what is observed to happen in the case of abscesses situated in the neighbourhood of the urethra, which, after their evacuation, whether spontaneous or artificial, often discharge purulent matter alone for a time, and then urine also. The true explanation, in both cases, probably is, that the matter, from not escaping with perfect freedom, accumulates in the cavity, so as to cause sufficient pressure for inducing ulceration of the denuded membrane. It is very seldom that a fistula of more than two months' standing will be found not

to have an internal aperture." (*On Diseases of the Rectum*, edit. 3, 1854, p. 20.)

The statements just quoted are somewhat perplexing and contradictory, but, the fact is, these abscesses really originate in a variety of ways, and may commence by any one of the foregoing methods. *In the first place*, small circumscribed superficial abscesses immediately beneath the integument of the verge of the anus are very frequently met with. These may arise, as M. Ribes has stated, from the suppuration and bursting of an internal pile into the rectum; but they may also be produced independently of hæmorrhoidal disease, from constipation, or any other irritating cause. The fistulæ resulting from these abscesses are usually of small extent, are altogether superficial to the sphincter muscle, and seldom give rise to burrowing of matter in different directions. *A second class of cases* consists of those described by Sir B. Brodie, as the result of ulceration of the proper coats of the bowel, and escape of fæcal matter into the surrounding cellular tissue. Analogous to these are the cases where the coats of the rectum have been perforated by some hard substance, such as fish bones, &c., which have been swallowed with the food. These abscesses usually extend outwards into the ischio rectal fossa, and unless they are speedily relieved by incision, or the skin happens to give way, the matter is likely to burrow in various directions. The fistulæ resulting from these are generally deeper than the sphincter muscle. *A third class of cases* corresponds to those described by Mr. Syme, and take their origin external to the mucous membrane, the opening through which is of subsequent occurrence. These cases are, in the writer's opinion, more frequent than those arising from ulceration of the mucous membrane; at all events it is very common to find, upon opening an abscess, and for some time subsequently, that the mucous membrane is denuded for a considerable extent, but the most careful search will fail to discover any opening into the intestine; whereas in fistulæ of long standing the internal communication is generally met with. This kind of abscess may commence in immediate connection with the coats of the bowel, and thence make its way outward, which Mr. Syme believes to be the usual mode; or it may commence as a phlegmonous abscess in the ischio rectal fossa, and extend inwards through the fibres of the levator and the proper fibres of the bowel, until the mucous membrane is denuded. This latter kind of abscess often arises from some direct local injury, such as a fall or blow upon the perineum, and it is in these cases that an early incision, before denudation of the mucous membrane has taken place, is especially called for, and is likely to be followed by permanent closure of the cavity, which will hardly occur if the abscess commenced in connection with the coats of the bowel. An excellent account of the different kinds of abscesses near the anus has been given by M. Velpeau. See *Dict. de Méd.* ed. 2, 1833, t. iii. p. 304, Art. *Abcès de l'Anus*.

The situation of the internal orifice of fistula in ano was also further investigated by M. Velpeau. In thirty-five cases examined by him, he found that a great majority opened at the entrance of the anus, or a few lines within, in accordance with the statement of M. Ribes. Three, however, had their orifice outside the villous membrane of the anus, whilst on the other hand there were four, in

which the opening was as high as an inch and a half, two inches, or two inches and a half, and a fifth even as high as three inches, and only just within reach of the finger. (*Dict. de Méd.* t. iii. p. 321.)]

The complete fistula is the most frequent form, but whether the case be a complete fistula, or a blind external one, that is, whether there be an opening in the skin only, or one there and another in the intestine, the appearance to the eye is much the same.

The method by which each of these states may be known is, by introducing a probe into the sinus by the orifice in the skin, while the forefinger is within the rectum.

[The internal orifice being then carefully sought for in the proper situation, *i. e.* just above the sphincter muscle, it may, in most instances, be discovered; but as it was formerly supposed to be situated at the upper extremity of the sinus, surgeons frequently failed to find it, and hence arose the opinion, that the blind external fistula was the most frequent variety of the disease. Sir B. Brodie maintains, that the internal opening is *always* present, and therefore does not admit the existence of an external blind fistula at all; but, as has been already explained, cases are sometimes met with, especially when the disease is not of long standing, in which no internal orifice can be discovered after the most careful search; and in addition to this, as Mr. Curling remarks, preparations may be met with in museums, which prove beyond all doubt that such a state of things is occasionally found.]

The track of the sinus may often be felt as a hard cord under the skin, and by careful examination, the course which it takes, and the existence of other sinuses branching from it, may be made out. Some inequality of surface, a projecting papilla, or slight excavation of the mucous membrane distinguishable by the finger in the rectum, will often indicate the situation of an internal aperture, and will afford a useful guide for the direction of the probe. The absence of this, however, must not be taken as a proof that a communication does not exist, for sometimes, after a fruitless search with the probe and finger, a little water injected along the sinus with a small syringe will be found to make its way into the rectum, and will thus demonstrate the existence of a communication.]

Sometimes the matter of an abscess, formed near the anus, instead of making its way out through the skin externally, near the verge of the anus, or in the buttock, pierces through the intestine only. This is what is called a *blind internal fistula*. In this case, after the discharge has been made, the greater part of the tumefaction subsides, and the patient becomes easier. If this does not produce a cure, which sometimes, though very seldom, happens, some small degree of induration generally remains in the place where the original tumor was; upon pressure on this hardness, a small discharge of matter is frequently made per anum; and sometimes the expulsion of air from the cavity of the abscess into that of the intestine may very palpably be felt, and clearly heard; the stools, particularly if hard, and requiring force to be expelled, are sometimes smeared with matter; and although the patient, by the bursting of the abscess, is relieved from the acute pain which the collection occasioned, yet he is seldom perfectly

free from a dull kind of uneasiness, especially if he sits for any considerable length of time in one posture. (*Pott*, op. cit. p. 96.)

TREATMENT OF FISTULA.

The methods of cure proposed and practised by our ancestors were three : viz. caustic, ligature, and incision.

The intention in each of these is the same : viz. to form one cavity of the sinus and intestine, by laying the former into the latter. The two first are now completely, and most properly, exploded.

For the treatment by incision, "the curved probe-pointed knife, with a narrow blade, is the most useful and handy instrument of any. This, introduced into the sinus, while the surgeon's forefinger is in the intestine, will enable him to divide all that can ever require division ; and that with less pain to the patient, with more facility to the operator, as well as with more certainty and expedition, than any other instrument whatever. If there be no opening in the intestine, the smallest degree of force will thrust the point of the knife through, and thereby make one ; if there be one already, the same point will pass through it. In either case it will be received by the finger in ano ; will thereby be prevented from deviating ; and being brought out by the same finger, must necessarily divide all that is between the edge of the knife and the verge of the anus." (*Pott*, op. cit. p. 39.)

Besides the operation with the probe-pointed bistoury, as described by Pott, surgeons often practise another with a silver director and sharp-pointed bistoury. The director is introduced into the sinus, and then into the rectum, either through the internal opening, if one already exists, or by making it gradually penetrate through the coats of the bowel if no internal opening can be discovered. Then the director is to be bent, so as to make one extremity of it project through the anus ; and the soft parts which lie over it divided, by passing the sharp-pointed bistoury along its groove. (See *Brodie*, in *Lond. Med. Gaz.* for 1835—36, p. 184.) When there are several sinuses, and any of them are left undivided, the operation will probably not bring about a cure ; hence the common maxim, that every sinus must be laid open.

[Whenever it can be found, the internal orifice should be included in the incision. Mr. Syme attaches great importance to this, and he thinks, that "in complete fistulæ the most extensive incisions will fail to afford permanent relief unless they include the internal opening ;" and "that the repetition of operations for this disease, which are so frequently heard of in practice, are, with few exceptions, referable to this mistake." (*On Dis. of the Rectum*, ed. 3, p. 38.) Sir B. Brodie also says, "if you make an artificial opening, and fail to find the real original opening, in three cases out of four you will be plagued afterwards. You have made an artificial opening, but the original one remains, and you go on dressing the sore, but there is a little infiltration of fæces and mucus into it that prevents it being healed. When you have made an artificial opening in the way I have stated, I advise you to do something more. Having made the artificial opening, and laid the fistula open into the gut, take a straight probe-pointed bistoury, introduce it into the rectum, turn its cutting edge

outwards, divide the sphincter muscle, and set that completely at liberty. This is better than merely laying open the sinus into the gut, where you cannot find the internal orifice ; but it is not so good as the operation where you can find it, because you have more bleeding, you give your patient more pain, and there is a larger wound to heal. (See *Lancet*, vol. i. 1843—44, p. 562.)]

The following remarks by Sir Benjamin Brodie deserve to be remembered :—"The advantage of the division of the sphincter is not merely theoretical. There are few cases, in which it will not greatly facilitate the ultimate cure, preventing the burrowing of matter, and the formation of fresh sinuses, and rendering the subsequent dressings more easy to the surgeon, and less painful to the patient. It is, however, to the more complicated cases of fistulæ that the division of the sphincter is especially applicable ; as, for example, where the sinus is of unusual extent, or where there are several sinuses, or where you are not certain that you have been able to detect the whole of them, or where the neighbouring parts are extensively indurated. It is quite a mistake to suppose, that there is any well-founded objection to even the most free division of the sphincter ; even in the first instance it scarcely interferes with the retention of the fæces, except they are actually liquid ; and the muscle never fails to become perfectly united, and afterwards perform its functions as well as ever. Nor have I ever known any hæmorrhage arise, which was not readily commanded by a dossil of lint introduced into the wound, and the pressure of the finger continued for a short space of time. If there be any considerable bleeding vessel, it is not difficult to secure it with the tenaculum and ligature ; but this is seldom necessary." (*Lond. Med. Gaz.* 1835—6, p. 184.)

[At St. Mark's Hospital for Fistula, &c., Mr. Salmon practises this free division of the sphincter in all cases, believing that it more effectually prevents any lodgment of matter, and thus renders the success of the operation a much greater certainty.

The treatment of *blind internal fistula* is to be conducted on the same principle as that of a blind external one ; that is, it must be converted into a complete fistula, and then be laid freely open into the bowel. If the situation of the cavity is distinguishable externally, it may be opened at once by an incision through the tissues which cover it ; if it is not sufficiently evident, it may be made so by the introduction of a bent probe from the rectum through the internal orifice of the fistula ; the point of the probe being made to project towards the integument, can then be cut down upon from without.]

The real difference, therefore, as Mr. Pott observed, "between this kind of case and that in which there is an external opening (with regard to method of cure), is very immaterial ; for an external opening must be made, and then all difference ceases. In this, as in the former, no cure can reasonably be expected, until the cavity of the abscess and that of the rectum are made one ; and the only difference is, that in the one case we have an orifice at or near the verge of the anus, by which we are immediately enabled to perform the necessary operation ; in the other, we must make one." (*Op. cit.* p. 96.)

Immediately after the operation, a soft dossil of

fine lint should be introduced (from the rectum) between the divided lips of the incision; as well to repress any slight hæmorrhage, as to prevent the immediate reunion of the said lips; and the rest of the sore should be lightly dressed with the same. Cramming the sinuses with lint, besides causing great pain, would prevent the free escape of purulent matter, and promote the formation of new sinuses. Sometimes it is advantageous to give a few drops of laudanum after the operation, on the principle specified by Sir Benjamin Brodie, namely, not with the view of relieving pain, but of occasioning costiveness, which will allow the dressings to remain undisturbed for two or three days. After this, a gentle aperient may be administered, which will prevent the ill effects of too long continued constipation, and, at the same time, bring away the first dressings. Instead of immediately applying dressings again, Sir Benjamin Brodie prefers a poultice for three or four days, until the first inflammation consequent on the operation has subsided. After this, he dresses the sinuses daily, either with dry lint, or with lint spread with some stimulating ointment, or soaked in a stimulating lotion; always observing the rule to dress lightly. The first dressing should be permitted to continue until suppuration renders it loose enough to come away easily; and all the future ones should be as light, soft, and easy as possible.

If a loose fungous kind of flesh has taken possession of the inside of the sinus, a slight touch of the lunar caustic will reduce it sooner, and with better effect on the sore, than any other escharotic whatever.

Modern writers also speak of a smooth adventitious membrane, which is found to line old fistulæ, and frequently to hinder the success of the operation. (See *Quarterly Journ. of Foreign Medicine, &c.*, No. 8.) But my own belief is, that a case hindered from getting well by this cause is very rare in comparison with others in which the cure is prevented by the matter being still more or less confined, and not having as free an outlet as circumstances demand.

Sometimes in attempting to cure what seems to be a common fistula, we find that it does not get well; and in the end a copious abscess is discovered higher up, which prevents the closing of the smaller sinus below. (See Brodie, in *Lond. Med. Gaz.* vol. for 1835, 1836, p. 28.) I have had opportunities of seeing several cases corresponding to this accurate description. In another place, Sir Benjamin Brodie, in adverting to a few cases which are met with, and kept from healing by some undetected sinus, relates the particulars of one instance, in which a lady had several sinuses near the rectum. Sir Benjamin Brodie laid open all he could find; but she continued uncured a considerable time, during all which she complained of uneasy sensations, which could not be accounted for. After repeated examinations, a sinus was detected high up, not more than an inch in length, and seemingly involving the levator ani. This having been laid open, a cure soon followed. See *Lond. Med. Gaz.* for 1835, 1836, p. 185.)

Fistulous sores, sinuses, and indurations about the anus, which are consequences of diseases of the neck of the bladder and urethra, called fistulæ in perinæo, require separate and particular consideration. (See FISTULA IN PERINÆO.)

Abscesses are frequently formed about the lumbar vertebræ, under the psoas muscle, and near the sacrum; in which cases, the bones are probably carious, and sinuses may run down by the side of the rectum, and burst near the fundament. The treatment of such sores and sinuses can have little influence on the remote situation where the collection of matter is originally formed. (See LUMBAR ABSCESS.)

Some years ago, M. Roux published a critique on the preference which English surgeons invariably give to Pott's method of operating for fistula in ano. The plan which he prefers, consists in the use of a kind of director, called a gorget, which is usually made of ebony or box-wood, and intended to be introduced within the rectum, with its concavity turned towards the fistula. A steel director, slightly pointed, and without a *cul-de-sac*, is then passed through the fistula, till the point comes into contact with the wooden gorget. A long, narrow, sharp-pointed straight bistoury is now introduced along the groove of the steel director, till its point meets the groove of the ebony gorget, by cutting upon which all the parts are divided which lie between the internal opening of the fistula and the anus. It may be objected to this method, that it is not always easy to make a director pass at once through the fistula into the rectum. This is acknowledged by Richerand, who adds, that, in this circumstance, the point of the director may be forced into the rectum, without lessening the chance of the success of the operation. (*Nosogr. Chir.* t. iii. p. 463, 464, ed. 4.) A flexible silver director will be more likely to follow the track of the fistula completely into the rectum than a steel one; and the finger of the surgeon will always do the office of the wooden gorget with greater convenience. The only purpose which such a contrivance answers, seems to Sir Benjamin Brodie to be that of saving the surgeon's fore-finger; but, in using it, an advantage is lost, that of the sense of touch; "and (says he) in my own practice, I have found that I could complete the operation better with my fore-finger than the wooden gorget." (*Op. et vol. cit.* p. 184.) M. Roux censures us for not *cramming* the wound with charpie; for he is not content with merely introducing into it a dossil of lint. (See *Parallèle de la Chir. Angloise, &c.*, p. 296, &c.) His countryman, Pouteau, however, long ago expressed his decided conviction of the inutility of cramming the wound with dressings to its very bottom, after the third day, when superficial dressings, and the renewal of them as often as cleanliness requires, will be fully sufficient. After the sinuses are healed, there is always a sort of fissure or chink left by the side of the anus. If the sinus has been deep, this chink will be deep in proportion; and then an inconvenience will follow, which may lead the patient to fear he is not cured, though he is so in reality. "The mucus of the rectum, sometimes stained with the fæces, will flow through it and stain the linen. But (as Sir Benjamin Brodie adds) this is only temporary; the chink, however deep, will gradually close, and the mucus will ultimately be retained as well as ever."

Operations for fistula in ano may be followed by very troublesome hæmorrhage; but this happens, I believe, chiefly in patients whose hæmorrhoidal vessels are enlarged, or where the surgeon deviates from the prudent advice delivered by

Sir Benjamin Brodie, with reference to such abscesses as are formed high up by the side of the rectum, and above the sphincter. In such cases, in opening the abscess in the first instance, he directs the lancet to be carried through the skin, by the side of the anus, until the matter flows. Then a probe-pointed bistoury is to be introduced, and the rectum divided at the lower part of the abscess, and the incision carried through the sphincter. It is quite unnecessary to lay the whole abscess open into the rectum, and it might give rise to dangerous hæmorrhage from vessels beyond the reach of the finger. (*Brodie*, op. et vol. cit. p. 186.)

[In like manner, when the fistula extends upwards by the side of the rectum, the internal orifice being in the usual situation, it will be sufficient to lay open the lower part of the fistula through the internal orifice into the bowel without interfering with the upper portion. It will be better, however, in such a case, to carry the knife freely through the sphincter, in order that there may be a ready outlet at once for any matter that continues to be secreted.]

Like all other mechanical injuries, operations for fistula may give rise to erysipelas, and in some rare examples, to traumatic tetanus. With respect to erysipelas, Sir Benjamin Brodie notices its occasional extension in a few instances up the mucous membrane of the rectum into other parts of the intestinal canal; a formidable disease, the symptoms of which are peculiar, but not described by any other writer. "The pulse (says Sir Benjamin Brodie) becomes very rapid, and, at the same time, weak; then it is irregular and intermitting. The abdomen is tympanitic, hiccough takes place; there is a great prostration of strength, and the patient often dies in the course of three or four days, sometimes sooner." On one lady, the attack began when the wound of the operation was nearly healed up, and she died in less than forty-eight hours. He considers that, in consequence of the great prostration attendant on it, the disease demands the free exhibition of cordials and stimulants. (See *Lond. Med. Gaz.* for 1835, 1836, p. 185.)

Abscesses near the rectum frequently occur in patients who are labouring under tubercles and abscesses of the lungs. Hence, Sir Benjamin Brodie very properly recommends surgeons, before they operate on a patient for fistula, to ascertain whether the lungs are sound. "Persons with diseased liver, and other visceral diseases (he observes), are also liable to the formation of these abscesses. The distinction of these cases from others, which occur in otherwise healthy subjects, is very important, inasmuch as the practice, which is proper in the one case, is quite improper in the other." (See *Lond. Med. Gaz.* vol. cit. p. 28.) He adds, if the patient labour under visceral disease, it is seldom that the abscess will heal; but if it should, the visceral disease will make increased progress, and the patient die sooner if the operation be performed than if it were let alone. (p. 29.) Every well-informed surgeon will likewise coincide in the prudence of not operating for a fistula, if stricture or carcinoma of the rectum exist; for, under these circumstances, the sinus will not heal, even if it be laid open.

Le Dran's Operations; Sharp's Operations; La Faye's Notes on Dionis. H. Bass, D. Fistula Ani feliciter curanda, in Halleri Disp. Chir. 4, 453. J. L. Petit, Traité des Mal. Chir. t. i. and ii. p. 113. Kirkland's Medical Surgery, vol. ii. Some of the best prac-

tical remarks ever published are contained in *Pott's Treatise on the Fistula in Ano*, in which he has offered also an excellent critique on the opinions of Le Dran, De La Faye, and Cheselden. *Sabatier, Méd. Syme, on Diseases of the Rectum, ed. 3rd, 1854.*

FISSURES OF THE ANUS,

As they are termed, consist of longish superficial ulcerations near the anus, between the converging folds of the fine skin and mucous membrane. When the sides of the anus are separated, and the patient is desired to strain, a narrow fissure is seen, the bottom of which is red, and the margins somewhat swollen and callous. But, as Dupuytren observed, it is frequently necessary, for the purpose of ascertaining how high it reaches, to introduce the finger into the rectum. It is more commonly situated at the sides and back of the anus than at the fore part of it; a favourable circumstance in relation to an operation, particularly in women, in whom this opening is divided from the posterior commissure of the vulva only by a thin partition. The ulceration rarely affects the whole thickness of the mucous membrane. (See *Dupuytren, Clinique Chir. t. iii. p. 283.*) Fissure of the anus is usually productive of violent lancinating or burning pain, which gradually augments, and lasts a considerable time after the patient has had a motion. In some cases, indeed, so extreme is the suffering, that the patient, from a dread of obeying the call of nature, refuses to do so as long as possible, or even nearly starves himself, to render the occasions for emptying the rectum less frequent. The severity of the case arises chiefly from a painful spasm of the sphincter muscle.

Baron Dupuytren makes a very useful and practical division of fissures of the anus into three kinds. Some are below the sphincter, affecting hardly any texture but the skin, and not the mucous membrane. These excite more or less pruritus, but cause little obstruction to the passage of the fæces. Fissures above the sphincter, involving the mucous membrane, can only be seen with the aid of a speculum. When the finger is passed into the rectum, a knotty hard cord is felt, and pressure on it creates acute pain. When the patient goes to stool, such fissures give rise to an indescribable sort of tenesmus, which ceases directly after the evacuation; and the excrement on the side nearest the disease, is covered with puriform or mucous, bloody fluid. Such fissures were found by Dupuytren to be commonly produced by the ulceration of internal piles, excited by the passage of indurated fæcal matter. Lastly, fissures on a level with the sphincter, are the worst, being attended

with agonising contraction of the sphincter, and other symptoms already specified.

Constipation and the spasm which it excites are amongst the predisposing causes of fissure of the anus. The indurated faecal matter, either by causing ulceration of the mucous membrane, or by immoderate distension of the passage, may bring on the complaint. The unskilful administration of clysters, especially with pointed rough pipes, is often the cause. Fissures of the anus are frequently met with in persons who have piles; and according to Dupuytren, the lodgment of venereal matter near the anus, as happens in many women, may lead to the complaint. Perhaps it would be more correct to say, that the contact of any irritating matter, or secretion, may have this effect.

The two first descriptions of fissure described by Dupuytren, may mostly be cured without any operation; some by dressing them with simple cerate, or ointment containing opium, mercurial preparations, &c.; others by emollient anodyne lotions or applications. But where the fissure was of the third description, he considered the operation first introduced by Boyer the quickest and surest means of cure. This consists in dividing the anus and sphincter with a probe-pointed bistoury, passed into the rectum, and cutting directly through the fissure, except when it lies forward towards the vagina in the female, or urethra in the male subject. [In these latter cases, he did not cut through the fissure, but divided the sphincter in the lateral direction. He did not consider it absolutely necessary to include the fissure in the incision, because he believed the spasmodic contraction to be the essential part of the disease, and thought that the ulcer would always heal if it were allowed to remain at rest a sufficient length of time, which is effectually secured by the division of the sphincter muscle.] When several fissures existed, Dupuytren sometimes made several cuts in different directions, from three to four lines deep. (See *Clin. Chir.* t. iii. art. 10.)

According to Boyer and Dupuytren, the spasmodic contraction of the sphincter is the real disorder, and the fissure is only a secondary effect. By putting a stop to this contraction, the disease is cured. With this view, Dupuytren tried what good could be done by the following application: *R.* Axungiae 3vj., extr. belladonnæ, plumbi acetatis ā ā 3j. Misc. A tent of linen or charpie, or a soft rectum bougie, of moderate size, smeared with this ointment, is introduced, and its diameter gradually increased to that of the forefinger. Dupuytren states, that the continuance of this treatment for a few days frequently relieves the pain entirely, and obviates all necessity either for caustic, or the division of the sphincter. Even when the plan does not cure, it always palliates, and therefore should be tried before the latter methods are resorted to.

Sir Benjamin Brodie has also spoken of the contraction of the sphincter as a distinct affection; and describes it as occurring chiefly in women disposed to hysteria; though sometimes in the male sex. He observes, however, that very often a small ulcer of the mucous membrane of the rectum accompanies the spasmodic contraction of the sphincter, and is always situated at the posterior part, opposite the point of the os coccygis. When the suffering is not excessive, relief may sometimes

be derived from purgatives, given to prevent the evacuations from being hard and figured, from an opiate suppository at night, and from the introduction of a bougie into the anus just before the patient has a motion. In worse cases, Sir Benjamin Brodie recommends the division of the sphincter with a straight probe-pointed bistoury. The forefinger is passed into the rectum, quite above the sphincter, as a guide to the bistoury. The fibres of this muscle are thick, and will require two or three strokes for their complete division. An opiate may be given to keep the bowels quiet for two or three days afterwards. Then a dose of castor oil may be exhibited. Simple dressings will suffice to heal the wound. (See *Lond. Med. Gaz.* 1834—35, p. 26.)

In females, the incision should never be made towards the vagina, for it will never heal properly in this situation, and the sphincter will not become perfect again; so that the patient will be left with an incontinence of fæces. In neither sex should the incision be directed towards the coccyx; because in this way only the inner or circular fibres of the sphincter can be divided, and not the outer layer which is attached to the apex of the os coccygis. The knife passes between the two lateral portions of this outer layer and simply splits or separates them; and the contractile power of the muscle remains, and interferes with the cicatrization of the wound. (Brodie, op. cit. 1836, p. 187.)

[Many surgeons do not believe with Boyer, that spasm of the sphincter is the primary cause of the disease, but consider the opposite explanation as the true one, namely, that the ulcer is the primary disease, and that the spasm is caused by the pain and irritation produced by the passage of the stools over the ulcerated surface. This latter view of the question has the support of M. Velpeau (see *Op. Surg.* translated by Mott, vol. iii. p. 1109), and it is also strongly urged by Mr. Quain, (*On Dis. of the Rectum*, p. 176.)

In support of this view may be mentioned the fact, that cases are not unfrequently met with in which spasm of the sphincter does not exist, or, at any rate, does not form a prominent symptom; it cannot therefore *always* be the cause of the disease; it would seem more correct, therefore, instead of subdividing the complaint, as Boyer did, into contraction with fissure and contraction without fissure, to speak of fissure with contraction and fissure without contraction.

Of late years many surgeons have advocated less extensive incisions than those originally recommended by Boyer. Mr. Copeland states, that in a simple ulcer the mere setting the mucous membrane at liberty by dividing it longitudinally so as to include the ulcer in the incision, is sufficient to effect a cure. Mr. Syme and, subsequently, many other surgeons, have inculcated a similar practice, and state that it has been attended with complete success in their hands; a further proof that the complaint does not depend altogether on the contraction of the muscle, or it would not be relieved by the mere scarification of the mucous membrane forming the base of the ulcer.

The milder plan of treatment just alluded to is now very frequently practised. It is doubtful, nevertheless, whether it can be depended upon to give such complete relief, and to effect so permanent a cure *in all cases*, as the incision through the sphincter. Mr. Salmon states, that he has repeat-

edly seen cases in which the slighter incision has failed to cure the disease, and he therefore still practises the free division of the muscle in all cases in which an operation is required.

It seems reasonable to suppose that the division of the muscular fibres becomes *essential* in proportion to the extent to which they are found spasmodically contracted.

Some of the French surgeons have lately practised *forcible dilatation* of the sphincter muscle. "The operator introduces his two thumbs into the rectum, and after having obtained a *point-d'appui* for his fingers against the tuberosities of the ischia, he forcibly separates his thumbs until they come in contact with the internal surface of the tuberosities. He experiences at first a resistance, then a sensation of internal laceration, and his two thumbs touch the bones." M. Nélaton "does not hesitate to say that this is certainly the best mode of treating fissures of the anus" (see *Elém. de Pathol. Chir.* tom. v. p. 80, 1858), a remark in which the majority of English surgeons are not very likely to coincide.]

EXCRESCENCES OF THE ANUS.

These cases are frequent, the growths receiving a variety of names, according to their supposed resemblance to things, as condylomata, mariscæ, and fici. Some are much firmer than others; some of them grow, in consequence of irritation of the skin of the anus, by the contact of rancid secretions, or purulent matter. Others are originally piles; for, as Sir Benjamin Brodie observes, when the cavities of external piles become obliterated, they generally form flaps of skin, which gradually waste; but sometimes diseased action takes place in them, and they become converted into excrescences, similar to those which grow from the nymphæ of women. Many excrescences about the anus and perineum are of middling consistence, between that of a wart and that of a polypus. I have cured a great number by stimulating applications, as the nitrate of silver, the tinc. ferri mur., the acetic acid, and the powder of savine, blended with subacetate of copper, or a solution of the sulphate of copper. But, in general, I remove the larger kinds with a bistoury. The bleeding, which may be at first copious, does not generally require a ligature, as it stops as soon as lint or linen dipped in cold water and a T bandage have been applied. (See HÆMORRHOIDS and RECTUM.)

PROLAPSUS ANI.

See *Rectum, Prolapsus of.*

IMPERFORATE ANUS.

As it is of the utmost consequence that this and other malformations should not remain long unknown, one of the earliest duties of an accoucheur, after delivery, is the examination of all the natural outlets of new-born infants.

The place in which the extremity of the rectum, or the anus, ought to be, may be entirely, or partly, shut up by a membrane, or fleshy adhesion. In other instances, no vestige of the intestine can be found, as the skin retains its natural colour over the whole space between the parts of generation and the os coccygis, without being more elevated in one place than another. In these cases, the intestine sometimes terminates in one or two *culs-de-sac*, about an inch upward from the ordinary situation of the anus. (See *Baillie's En-*

gravings, fasc. iv. tab. v.) Sometimes it does not descend lower than the upper part of the sacrum; sometimes it opens into the bladder or vagina. Dr. Palmer dissected a case, where the colon, after reaching the vicinity of the left kidney, began, as it descended, to form a sigmoid flexure; but previously to its arrival at the concavity of the left ilium, made a sudden turn to the right, and, crossing the psoas muscle, reached the projection of the sacrum, where it terminated, *without entering the pelvis at all*. With this malformation was combined an imperforate meatus urinarius, and other considerable deviations of the genital organs from their natural structure. (See *Medico-Chir. Journ.* vol. i. 8vo. Lond. 1816.)

Sometimes the colon terminates in a sac, and the rectum is entirely deficient. (See *Beauregard*, in *Journ. de Méd.* i. 66.)

[Dr. Bushe records a case in which the rectum terminated by two extremities, both in the median line, one being a little anterior than natural, the other about an inch further back. The posterior was the smaller of the two, and did not discharge more than one third of the fæces. (*On Diseases of the Rectum*, p. 44. New York, 1837.)]

In cases of imperforate anus, if a speedy opening be not made for the fæces, the infants soon perish, with symptoms similar to those of a strangulated hernia. Mr. A. C. Hutchinson thinks it advantageous, however, not to operate till the expiration of from twenty-four to sixty hours after birth, as he conceives that, within this period, no great inconvenience will arise, and the distension of the rectum with meconium will be a guidance to the surgeon in making the incisions. (See *Obs. in Surgery*, ed. 2.) After ascertaining the complaint, which is an easy matter, the surgeon should endeavour to learn, whether the anus is merely shut by portions of skin, a membrane, or a fleshy adhesion; or whether the anus is altogether wanting, in consequence of the lower portion of the cavity of the gut being obliterated, or the rectum not extending sufficiently far down.

When merely a thin production of the skin closes the opening of the rectum, the part producing the obstruction is somewhat different in colour from the neighbouring integuments, being usually of a bluish or livid hue, in consequence of the accumulation of the meconium under it. The meconium, propelled downward by the viscera above, forms a small roundish prominence, which yields like dough to the pressure of the fingers, but immediately projects again when the pressure is removed. When a fleshy adhesion closes the intestine, the circumstance is obvious to the eye, if the part protrude, as is generally the case; greater hardness and resistance are felt than when there is merely a membrane; and the livid colour of the meconium cannot be seen through the obstructing substance.

These last circumstances are of themselves enough to convince the surgeon of the necessity of an operation; but they do not clearly show, whether the intestine descends as far as it ought, in order to form a proper kind of anus. Complete information on this point can only be acquired after the obstructing substance has been divided, or else after the child's death, when the operation has proved ineffectual. Though there be no mark to denote where the anus ought to be situated, and no degree of prominence, yielding, like soft dough, to

the pressure of the fingers, and rising again when such pressure is removed; yet the rectum may still exist, and have a cavity, as far as the membrane, or adhesion, closing it.

When the anus is simply covered with skin, and its place indicated by a prominence, arising from the contents of the rectum, we have only to make an opening with a knife, sufficient to let out the meconium. Another cut may then be made across the first, and the four angles removed. About two years ago, I performed this operation, and the little patient was saved. A piece of bougie, or what is better, a portion of elastic gum catheter, is afterwards to be introduced, in order to keep the opening from closing. If the anus be only partly closed by a membrane, the opening may be dilated with tents or bougies; but, if the aperture be small, it is preferable to use the bistoury for its enlargement.

When no external appearance denotes where the situation of the anus ought to be, the case is more serious and embarrassing; and this, whether the intestine be stopped up by a fleshy adhesion, or the coalescence of its sides, or whether a part of the gut be wanting.

However, it is the surgeon's duty to do everything in his power to afford relief. For this purpose, an incision an inch long, or rather more, is to be made in the situation where the anus ought to be, and the wound is to be carried more and more deeply in the natural direction of the rectum. The cuts are not to be made directly upwards, nor in the axis of the pelvis; for the vagina or bladder might thus be wounded. On the contrary, the operator should cut backward, along the centre of the concavity of the os coccygis, where there is no danger of wounding any part of importance. In all cases of this kind, the surgeon's finger is the best director. The operator, guided by the index finger of his left hand, introduced within the os coccygis, is to dissect in the direction above recommended, until he reaches the meconium or has cut as far as he can safely reach with his finger. If he should fail in finding the meconium, as death must unavoidably follow, one more attempt ought to be made, by introducing, upon the finger, a middle-sized trocar, in the direction best calculated to reach the rectum, without danger to other parts, viz. upwards and backwards in the median line. Should this attempt prove successful, the canula may be left in the puncture and secured there with tapes, so as to afford an outlet for the fæces. In some observations on this subject, addressed to the Medical and Chirurgical Society by Mr. A. Copland Hutchison, he recommends an elastic gum catheter to be substituted for the canula, after a week; and, when the tube can be dispensed with, a sponge tent, or piece of bougie, to be worn twelve out of the twenty-four hours. (See *Obs. in Surgery*, ed. 2, 1826.)

In an interesting case, recorded in Langenbeck's Surgical Bibliotheca, the imperforate state of the anus was not discovered till the evening of the twelfth day from the child's birth, when hiccough and convulsions had come on. M. Wolff found the abdomen protuberant, hard, and painful when handled, and the child was suffering from nausea, vomiting, and great depression of strength. Next day, he introduced a lancet a few lines in front of the os coccygis, to the depth of an inch, without finding the rectum. The puncture was then carried to the depth of two inches, but without

effect. With a pharyngotomus, however, he now succeeded in piercing the rectum; and a glyster was administered, which brought away some meconium. Under the use of glysters and tents, the child soon recovered.

By such proceedings, many infants have been preserved, which would otherwise have been devoted to certain death. Hildanus, La Motte, Roonhuysen, Mr. A. Copland Hutchison, and others, have successfully adopted the practice. Mr. B. Bell met with two cases in which the intestine was very distant from the integuments, yet he succeeded in forming an anus, which fulfilled its office tolerably well for several years; though he found it difficult to keep it pervious. As soon as he removed the dossils of lint and other kinds of tents used for maintaining the necessary dilatation, such a degree of contraction speedily followed, that the evacuation of the intestinal matter became difficult. He employed, at different times, tents made of sponge, gentian root, and other substances which swell on being moistened. But they always produced such pain and irritation that it was impossible to persevere in their use. Tents of soft lint dipped in oil, or rolls of bougie-plaster, were found to cause less irritation than those composed of any other materials.

Though keeping the opening dilated may seem simple and easy to those who have had no opportunities of seeing cases of this description, it is far otherwise in practice. Mr. B. Bell assures us that he never met with any disease that gave him so much trouble and embarrassment, as he experienced in the two cases of this sort which occurred in his practice. Although, in both instances, he made the openings at first sufficiently large, it was only by very assiduous attention for eight or ten months that the necessity for another operation, and even repeated operations, was prevented. When only the skin has been divided, the rest of the treatment is, doubtless, more simple; for then nothing more is requisite than keeping a piece of lint, for a few days, in the opening made with the knife. But, when the extremity of the rectum is at a certain distance, though we may generally hope to effect a cure, after having succeeded in giving vent to the intestinal matter; yet the treatment, after the operation, will always demand, for a long while, a great deal of attention and care on the part of the surgeon. In a highly interesting example, recorded by Mr. Miller of Methven, such was the tendency to closure of the new opening, that he was obliged to repeat the operation ten times before the child was eight months old. (See *Edin. Med. Journ.* No. 98, p. 62.) Notwithstanding all these operations, and another one of two hours and three quarters' duration performed several years afterwards for the extraction of an alvine concretion, equal in size to a turkey's egg, the power of the sphincter was perfect.

[The cause of this contraction may be thus explained. The lost portion of the intestine can never be restored; it is a fistula which is substituted in place of the natural tube, and the species of mucous surface, which ultimately becomes developed but very imperfectly, represents the natural lining of the bowel. (See *Velpeau, Op. Surg.* Mott's Trans. vol. iii. p. 1090.) To obviate this inconvenience from subsequent contraction, and also to prevent the irritation caused by the passage of fæcal matters over the raw

surface, Amussat advised that the edge of the mucous membrane should be drawn down and stitched to the edges of the opening in the integument. As Mr. Erichsen remarks, however, this very desirable suggestion can only be carried into effect when the intestine terminates at a short distance from the surface. If the perineal incision were two or three inches in depth, there would be little probability of the surgeon being able to bring down the intestine to such an extent. In a case in which he attempted to do so, he found the gut too firmly fixed to be moved by any traction that it would have been safe to have employed. (See *Erichsen, Science and Art of Surgery*, p. 790.)

The probability of success in these cases may be considered as, in some measure, proportioned to the depth of the necessary incision. An infant was brought to University College Hospital with an imperforate anus; Mr. Liston, after carrying the incisions to the depth of three inches, made a small opening into the intestinal canal, as indicated by the discharge of fetid gas, and a small quantity of meconium. A piece of bougie was introduced to maintain the opening; but the child died in a very short time, and there was no opportunity of ascertaining the state of the parts. In a case like that recorded by Dr. Palmer, to which I have above adverted, the inutility of any attempt to discharge the fæces by an operation, in the usual site of the anus, must be sufficiently obvious. (*Medico-Chir. Journ.* vol. i. p. 181.)

Sometimes, while the anus appears pervious and well-formed, the infant suffers the same symptoms as if there were no anus at all. The reason of this depends upon the intestine being occasionally closed by a membranous partition, situated more or less upward, above the aperture of the anus. This case is in fact an imperforate rectum, rather than an imperforate anus. (*Courtial, Nouvelles Obs. sur les Os*, p. 147; *John Wayte*, in *Edin. Med. and Surgical Journ.* April, 1821; and *Cases in Hutchison's Obs. in Surgery*, ed. 2.)

[Dr. Bushe mentions a case in which he found two partitions, one about half an inch from the anus, and the other three-quarters of an inch higher up. (*On Dis. of the Rectum*, p. 40.)]

Sometimes the symptoms are owing not simply to an interruption of the cavity of the intestine, but even of its parietes; and thus the colon may be separated entirely from the rectum. (*Andral. Précis, d'Anat. Pathol.* t. ii. p. 143.) Such erroneous formations may be suspected, when an infant, whose anus is externally open, does not void any excrement for two or three days after its birth, and especially when urgent symptoms arise, such as swelling of the belly, vomiting, &c. We are now to endeavour to ascertain, whether the rectum is impervious above the anus, by attempting to inject glysters, or introducing a probe. If the gut be shut up, there is nothing to be done but having recourse to the method described above, and forming a communication by means of a bistoury guided on the finger, or else with a pharyngotomus. If the obstacle should only consist of a transverse membrane, the operation will be easy, and its success highly probable; but if there should be an internal obstruction of the intestinal canal, from total deficiency of some part of its parietes, the case is infinitely more serious.

In the case recorded by Mr. Wayte, the membranous septum was felt by the finger, about an

inch from the verge of the anus. It was pierced with a pointed probe, which was followed by a hydrocele trocar, and afterwards by a bougie of larger dimensions. On withdrawing the latter much meconium, mixed with fæces, escaped, and continued to be frequently discharged. In a week, however, the opening closed, and a fresh puncture was made, which was maintained by the frequent introduction of bougies. The child proceeded tolerably well until the end of another week, when the passage was again much contracted, and the abdomen proportionably distended. On the twentieth day from birth, a full-sized trocar was used for restoring the opening, which, however, again had a tendency to close, but was afterwards dilated by introducing, twice a day, bougies, which were increased in size, until a rectum bougie of middling size could be passed. The boy now rapidly improved, and every hope of perfect recovery was entertained, but disease of the os coccygis ensued; and at the end of six months, the little patient died hectic. (See *Edin. Med. and Surg. Journ.* vol. xvii.)

When the anus is imperforate, the intestine sometimes opens into the vagina in the female; or into the bladder, or urethra, in the male; there being, as Andral expresses himself, a tendency in the terminal orifices of the digestive, urinary, and genital organs to be confounded together, and to form a common cavity more or less analogous to the cloaca of birds. (*Précis d'Anat. Pathol.* t. ii. p. 144; *Dumas*, in *Recueil Périodique de la Soc. de Méd.* t. iii. No. 13; *Leveillé, Rapport des Travaux de la Soc. Philom.* vol. i. p. 145; *Murray Diss. Atresi Ani vesicalis*, Ups. 1794; *Act. Nat. Cur.* vol. viii. Obs. 24; vol. ix. Obs. 11; *Reestel*, in *Mursinna's Journ. für die Chir.* br. i. p. 547; *Obs. Med.* Decad. ii. No. 2; *Velpeau, Nouv. Elém.* t. iii. p. 977.) The first case is the least dangerous of such malformations. The intestine may terminate at two places at the same time, viz. at the usual place, so as to form a proper anus, more or less perfect; and also in the vagina. If the rectum were to terminate at the lower and posterior part of the vulva, of which M. Brachet has lately published an example, the making of a new anus in the proper situation would be unattended with difficulty. A director should be passed into the rectum through the opening already existing, and an incision made, under the guidance of this instrument, from the perineum towards the coccyx in the natural situation of the anus, through all the textures covering the extremity of the rectum. A canula is then to be fixed in the bowel, at the posterior part of the wound, by which means the front of the incision would have an opportunity of healing, and the fæces take their right course. This operation was recommended by Vicq d'Azyr. M. Velpeau sees no occasion for the suture advised by M. Martin for the union of the anterior part of the wound, and suggests that sometimes it may be advantageous not to divide the recto-vaginal septum at all, but to pass a blunt curved instrument from the vaginal fistula to the lower end of the bowel, and then make a puncture into the latter through the skin. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. iii. p. 979.)

When the two openings are exceedingly small, and the fæces cannot readily pass out, even with the aid of glysters, the opening of the anus ought to be enlarged with a knife, and kept dilated with a

canula. The communication with the vagina will then gradually close.

For the most part, the intestine has but one opening in the vagina. In this circumstance, the surgeon should make an incision in the place which the anus ought to occupy. The natural channel of the fæces being thus opened, less excrement will pass out of the vagina; and by the introduction of a tube into the new anus, the communication between the rectum and vagina will be obliterated and a perfect cure accomplished; an instance of which is recorded by M. Lépine. (See *Dict. de Méd. et de Chir. Prat.* t. iii. p. 121.) The opening between the intestine and vagina is sometimes too small for the due evacuation of the fæces, and the infant is then exposed to the same sort of dangerous symptoms as if the rectum had no opening at all.

In male infants, the rectum sometimes opens into the bladder; and, in these circumstances there is generally no anus. The case is easily known, by the meconium being blended with the urine, which acquires a thick greenish appearance, and is voided almost continually, though in small quantities. Only the most fluid part of the meconium is thus discharged. The thicker part, not getting from the rectum into the bladder, nor from the bladder into the urethra, greatly distends the intestines and irritates the bladder, producing in the end fatal symptoms. For a few days, however, the meconium may be diluted, and voided with the urine. An infant, whose meconium came away through the urethra, seen by M. Velpeau, lived nearly a week. (*Nouv. Elém. de Méd. Opér.* t. iii. p. 977.) In all such cases one thing is certain, viz. that without the speedy interference of art to form an anus, capable of serving as an outlet to the fæces, with which the urinary organs cannot remain obstructed, the infant will inevitably die. This case must, therefore, be treated on the same principles which apply to the foregoing examples. Though we can hardly hope to prevent altogether the inconveniences resulting from the rectum opening into the bladder, since even a new passage will not completely hinder the fæces from following the other course; yet we shall thus afford the child the only chance of preservation which its condition will allow.

Instances are also upon record, where the rectum opened into the urethra (*Bresl. Samml.* 1718, p. 702; *Hist. de l'Acad. Royale des Sciences*, 1752, p. 113; *Hochstetter*, in *Med. Wochenblatt*, 1780, No. 18; 1783, No. 19; *Kretschmar*, in *Horn's Archiv.* b. i. p. 350.)

[These cases may perhaps be distinguished from each other by the fact that, when the opening is urethral, a small jet of meconium will generally precede the passage of the urine, whereas when it is vesical, the meconium and urine will be mixed. (*Bushe, On Dis. of the Rectum*, p. 42.)

Mr. Fergusson operated successfully on a case in which the rectum terminated in the membranous part of the urethra. The child lived till he was six years old, when he died of disease of the lungs. Occasionally when his bowels were loose, a few drops of fæces would come by the urethra, and he was wont also to discharge part of his urine by the artificial opening into the rectum. In the operation, the rectum was first sought for in its natural situation, but without success. Some meconium being then observed to escape by the urethra, it was thought that the rectum terminated in the

bladder, and an incision was made, as it was believed at the time, in the neck of the bladder, through which the meconium escaped. On examination of the parts, after death, however, this was found not to have been the case, but the bowel terminated in the membranous portion of the urethra by an aperture about the size of a lancet puncture. (See *Ed. Med. and Surg. Journal*, vol. xxxvi. p. 363, and *Op. Surg.* ed. 3, p. 740.)

Cruveilhier saw an infant in which the rectum opened under the glans penis, through a canal formed in the substance of the raphè of the scrotum. (*Anat. Pathol.* pl. vi. 1re livr.)

[Mr. South met with a somewhat similar case. There was no anal orifice in the usual situation, but in front of the scrotum, and in the track of the raphè, there was a small opening, just large enough to admit a probe, and through this, when the child cried, a small quantity of meconium passed. There was a slight protrusion in the natural position of the anus when the child cried; Mr. South therefore made an incision at this part, and succeeded in finding the rectum at the depth of an inch from the surface. The child recovered from the operation, and lived till adult age, but the unnatural canal under the penis always remained pervious, and small quantities of stool occasionally escaped from it. (See *South's Trans. of Chelius*, vol. ii. p. 329.)

There are no satisfactory data to enable us to estimate the proportion of mortality in cases of imperforate anus, but it is unquestionably very great; probably of the whole number of children born with this malformation the survivors do not amount to more than one tenth.]

In cases in which an outlet for the fæces cannot be procured by any of the methods pointed out above, Littre proposed, in 1720, to make an opening in the sigmoid flexure of the colon, above the left groin, and thus form an artificial anus. In 1788, Dumas tried the plan on an infant, which died on the tenth day. In 1793, it was practised with complete success, by M. Duret, of Brest; and M. Pilore, of Rouen, had an equally fortunate case. But the infant, on whom Desault operated in 1794, lived but four days afterwards. M. Ouvrard, of Angers, and M. Roux, of Paris, lost also the two children on whom they made the experiment. (*Velpeau, Nouv. Elém. de Méd. Opér.* t. iii. p. 983.) M. Duret cut into the abdomen at the lower part of the left iliac region: and, having opened the sigmoid flexure of the colon, he fixed it near the wound. The child was saved by the formation of an artificial anus; but at the age of twenty-five months, it continued to be troubled with a prolapsus of the lining of the bowel. (See *Recueil Périodique de la Soc. de Méd.* t. iv. No. 19; and *Sabatier, Méd. Opératoire*, t. iii. p. 836, ed. 2.)

Callisen conceived, that the descending colon might be most easily got at by making an incision in the left lumbar region, along the edge of the quadratus lumborum muscle, and opening that intestine between the two layers of peritoneum, which fix it in its situation. Thus he calculated that all necessity for cutting into the cavity of the peritoneum itself would be obviated. (*Syst. Chir. Hodiernæ*, t. ii. p. 688, 689, ed. 1800.) The operation was tried in one case by M. Roux, but in two hours the infant perished. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. iii. p. 984.)

[Callisen's proceeding has been modified by Amus-

sat, who made the incision in the transverse instead of the vertical direction. For a further description of these operations, the reader is referred to the article on *Intestinal Obstructions*. The mortality which has attended their performance, in cases of imperforate anus, is very great. It is stated by Amussat, that of twenty-one children thus operated upon, only four ultimately recovered.]

ARTIFICIAL ANUS.

Anus Anormale, Dupuytren; Intestinal Fistula, Teale; Fæcal Fistula.—Artificial anus signifies an accidental opening in the parietes of the abdomen, to which opening some part of the intestinal canal tends, and through which a variable quantity, or even the whole of the intestinal matter or of the fæces, is involuntarily discharged.

[It may be the result of injury to some part of the intestinal canal, from penetrating wounds, mortification, or other causes; or it may be produced intentionally by the surgeon for the purpose of saving life, in cases of otherwise irremediable obstruction. In the present article, the first class of cases only will be treated of; and the reader is referred to the article on *Intestinal Obstructions* for a description of the operation to form an artificial outlet for the fæces. Mr. Teale gives the name of Intestinal Fistula to those cases in which the preternatural opening is the result of injury, and restricts the term Artificial Anus to those in which it is really produced *artificially* by the surgeon. Others distinguish by the name of *fæcal fistula* those cases in which a small proportion only of the contents of the bowel makes its escape by the unnatural opening, and apply the term *artificial anus* to those in which the whole, or nearly the whole, of the intestinal matter is so discharged.]

Of all the infirmities which assail the human race, none is more annoying and disgusting than an artificial anus; and, as a modern writer exclaims, what a wretched spectacle does a person exhibit, from whom the bilious alimentary matter and excrement are every instant involuntarily discharged! In vain is the aid of pouches, reservoirs, and boxes, for the palliation of his dreadful affliction; to him society is lost; and he is for ever doomed to live a solitary and miserable life. Such, at all events, was the sentence pronounced by science, until the genius of Dupuytren came to reform, and restore to the world the unfortunate individuals, who seemed to be for ever banished from it. (*Leçons Orales de Clinique Chir.* t. iii. p. 193.)

Excepting in those cases where the preternatural opening is purposely made by the surgeon, an artificial anus is always preceded by an injury of the intestinal canal, either by a penetrating wound, or by ulceration of the bowel, and the bursting of an abscess externally; or by an accidental wound of the gut in the operation for hernia; or, lastly, and most commonly, by mortification of the bowel, the effect of the long continuance of the strangulation of the part.

Foreign bodies, swallowed by mistake, have sometimes irritated the bowel, and caused it to become adherent to the peritoneum lining the parietes of the abdomen; then ulcerative inflammation ensued, followed by fæcal abscess, and a fistulous opening, or true artificial anus. In a few uncommon instances worms, of the lumbrici kind, have caused the same consequences.

All these cases are further divisible into such as

are attended with a destruction of a portion of the intestinal tube; and into those which are not accompanied with any such loss of substance.

When once an artificial anus has been formed, it is a solution of continuity produced in the bowel and parietes of the abdomen, which are completely adherent to one another. The opening, in whatever way occasioned, is most commonly roundish, but sometimes of an irregular shape. Its diameter varies from a few lines to an inch or more. In the majority of persons, its edges are thick, depressed, adherent to the subjacent parts, inclined towards the abdominal cavity, and immediately continuous with the mucous membrane of the bowel. A reddish circle denotes the place of their junction. The neighbouring integuments have radiating furrows in them, *en cul de poule*, analogous to what is observed near cicatrices in general; and notwithstanding the most minute attention to cleanliness, the matter evacuated irritates the skin, bringing on an erysipelatous redness, or excoriations of variable depth. (*Dupuytren, Clin. Chir.* t. ii. p. 196.)

Whatever may be the kind of injury which the bowel has sustained, one thing here invariably happens, viz. the adhesion of the two divided portions of the intestine to the edge of the opening in the parietes of the abdomen. This occurrence, which has the most salutary effect in preventing extravasation of the contents of the bowel into the cavity of the abdomen, is produced by the inflammation which precedes gangrene and follows wounds. (See *Œuvres Chir. de Desault*, t. ii. p. 352—354.) In hernia, the adhesions *precede* the destruction of the parts; in wounds, they *follow* the division of the bowel; and hence, in these last cases, the solution of continuity frequently brings on a fatal effusion. The adhesions never ascend far along the extremities of the bowel; which, being only contiguous, and covered by a smooth membrane, as in other parts of them, leave between them a sort of *cul-de-sac*, the entrance of which is towards the belly, while the apex is directed towards the skin. It is into this *cul-de-sac* that, in certain individuals, the abdominal viscera protrude, so as to occasion herniæ; which push the artificial anus outwards, compress, displace, and otherwise complicate it. (See *Dupuytren, Clinique Chir.* t. ii. p. 198.)

When, in strangulated hernia, the case is not relieved by the usual means, or when the necessary operation has not been practised in time, the protruded bowel sloughs; the adjoining part of it adheres to the neck of the hernial sac; and the gangrenous mischief spreads from within outwards. If the patient live long enough, and an incision in the tumor be not now practised, one or more openings soon form in the integuments, and through these apertures the fæces are discharged until the separation of the sloughs gives a freer vent to the excrement. But when an incision is made, the fæces are more readily discharged; and, as Mr. Travers has related, this is sometimes the best mode of relief. "In the ordinary situation of hernia, the portions of intestine, embraced by the stricture, occupy a position nearly parallel. Their contiguous sides mutually adhere; in the remainder of their circumference they adhere to the peritoneum, lining or forming the stricture. The existing adhesion of the contiguous sides, strengthened by the adhesion of

the parts in contact, ensures a partial continuity upon the separation of the sphacelated part. The line of separation is the line of stricture. It commences on that side of the gut which is in direct contact with the stricture. As the separation advances, the opposite adhering sides may perhaps recede somewhat, and a little enlarge the angle of union. But, it is ever afterwards an angle; and where the peritoneum is deficient, the canal is simply covered in by granulations from the cellular membrane of the parietes, coalescing with those of the external or cellular surface of the peritoneum." (*On the Process of Nature in repairing Injuries of the Intestines*, p. 360.) It must be confessed, that few surgeons have entertained sufficiently accurate ideas of the changes which happen around the wounded or mortified portion of intestine, when an artificial anus is produced; and though Desault's account was excellent, so far as it went, it was not until the year 1809, when Scarpa published his valuable work on Hernia, that the whole process of nature on such occasions was completely elucidated. The hernial sac (says he) does not always partake of gangrene with the viscera contained in a hernia; and even when it does slough, since the separation of the dead parts happens on the outside of the abdominal ring, there almost always remains in this situation a portion of the neck of the hernial sac perfectly sound. It may be said, therefore, that, in all cases, immediately after the detachment of the mortified intestine, whether it happen within, or on the outside of the ring, the two orifices of the gut are enveloped in the neck of the hernial sac, which soon becoming adherent to them by the effect of inflammation, serves for a certain time to direct the fæces towards the external wound, and to prevent their effusion into the abdomen. In proportion as the outer wound diminishes, the external portion of the neck of the hernial sac also contracts; but *that part, which embraces the orifices of the intestine, gradually becomes larger, and at length forms a kind of membranous, funnel-shaped, intermediate cavity, which makes the communication between the two parts of the bowel.* However, according to Scarpa's investigations, this adhesion of the neck of the hernial sac round the two orifices of the gut, does not hinder the latter from gradually quitting the ring, and becoming more and more deeply placed in the cavity of the abdomen. The base of the above-described funnel-shaped membranous cavity corresponds to the bowel, and its apex tends towards the wound, or fistula.

But, in relation to this part of the subject, there are some other circumstances which every surgeon should well understand. I allude to the exact position of the two portions of the bowel, with respect to each other, the direction of their orifices, the angle or ridge between them, and the difference in their diameters. The first of these circumstances, viz. the position of the two parts of the bowel, was correctly described by Saviard, Morand, and Desault; and, as we have seen, is pointed out by Mr. Travers, who represents them as occupying a position nearly parallel, and cites an interesting observation recorded by Pipelet. The patient was a woman fifty-six years old; the loop of spoiled gut was from five to six inches long: the contents of the bowel were discharged through the wound for a considerable time, and an artificial anus was

established. Some accidental obstruction occurred; a purgative was given, which operated in the natural way, and in fifteen days the wound was healed. She lived in perfect health to the age of eighty-two, when she died of a disease not connected with this malady. Pipelet examined the body, and has given a figure representing the union. The line of the intestine formed an acute angle, where it adhered to the peritoneum, opposite to the crural arch. The cylinder is evidently much contracted. Pipelet particularly dwells upon the angular position, and constriction of the tube at the point of union. The lower continuation of the intestinal tube was also remarked to be more contracted than the upper portion; a circumstance correctly referred, by Mr. Travers, to the undilated state of the bowels, situated between the artificial and the natural anus. (See *Mém. de l'Acad. de Chir.* t. iv. p. 164; and *Travers, On Injuries of the Intestines*, p. 364.) The two ends of the bowel, as Scarpa has observed, are found lying in a more or less parallel manner by the side of each other; the upper with its orifice open, and directed towards the external wound by the fæces, which issue from it; while the lower, which gives passage to nothing, becomes less capacious, and is retracted further into the abdomen; or, as Dupuytren observes, the two terminating portions of bowel pass into the abdomen, sometimes crossing, sometimes coiling over one another; in other instances, running parallel; but most frequently diverging at a more or less acute angle. (See *Dupuytren, Clinique Chir.* t. ii. p. 202.) According to Scarpa, the breach in the intestinal canal is never repaired by the orifices of the upper and lower portions of the bowels reuniting, coalescing, and running as it were into each other. Indeed, they meet at a very acute angle; the axis of one does not correspond to that of the other; and their orifices never lie exactly opposite each other. It is, in short, by means of the funnel-shaped cavity, formed by the remains of the hernial sac, that the two parts of the bowel communicate; and the fæces, in order to get from the upper into the lower continuation of the intestine, must first pass in a semicircular track through that funnel-shaped cavity, there being between the orifices of the bowel, *a considerable projection, or jutting angle, forming a material additional obstacle to the direct passage of the fæces from the upper into the lower portion of the intestinal tube.* (Scarpa sull' *Ernie Memorie*, *Nat. Chirurgische*, Milano, 1809.)

This promontorio, as it was called by Scarpa, or éperon, as it is named by the French, was mentioned both by Saviard and Morand. It consists, in fact, of the part of the bowel which has been spared by gangrene, or a wound, in the direction towards the mesentery; and it advances more or less towards the skin, in proportion as the bowel has experienced a greater or lesser loss of substance, or a greater or lesser change of direction. When the bowel has only been wounded, or the seat of a small slough, and it pursues its natural course, the projection is trivial and concealed; but very large, reaching the level of the skin, when the whole circumference of the bowel has been destroyed; and, in consequence of the loss of substance, its two ends meet at an acute angle, or run parallel to one another. In the first case, there is between the two orifices of the bowel a cylindrical channel, more or less deep, which may still con-

vey matters from the upper to the lower end. This case is most easy of cure. In the other, no trace of such a channel is discoverable; and the jutting angle, the *éperon*, between the two orifices of the intestine, forms a barrier which the intestinal matter cannot pass. Thus the difficulties are greater, and the resources of surgery less certain. (See *Dupuytren, Clin. Chir.* t. ii. p. 203.) Whatever may have been the original state of this projecting angle, after a certain time it does not divide the bottom of the funnel-shaped tube, where the orifices of the intestine are, into two equal parts; because it is propelled towards the lower portion of the bowel, by the pressure of the matters passing through the orifice of the upper end. By degrees the orifice of the lower end becomes covered by it as by a valve, and is detected with difficulty.

Towards the interior of the bowel, Dupuytren found that the *éperon* had constantly the shape of a crescent, while towards the cavity of the abdomen the two equal halves of it diverged from one another to receive the mesentery in the interspace. The *éperon*, therefore, is composed of a single wall only at its sharp edge, and everywhere else it consists of two parietes, leaving between them a triangular interval, which becomes greater as the two portions of the bowel recede from one another in their course into the abdomen. From this latter disposition, says Dupuytren, a fact of the highest importance arises; viz. that the cavities of the two ends of the intestine are separated from one another by a double septum, the surfaces of which, on the side towards the belly, are smooth, and free from all adhesion together. To get, therefore, from one of these cavities into the other, through their parietes, the cavity of the peritoneum must of necessity be pervaded: hence the difficulty and danger in trying to form a communication between the two ends of the bowel by attacking the septum between them. (See *Dupuytren, Clinique Chir.* t. ii. p. 204.)

Another interesting circumstance, explained by Dupuytren, is, that the jutting angle, and double septum, the continuation of it, are not invariably so fixed as to be totally incapable of advancing or receding; but, being connected with the mesentery, they are, in a certain degree, obliged to follow the movements communicated by it to them. Sometimes, when hernia is combined with adhesions, the mesentery, which becomes elongated, and forms a cord between the spine and the displaced bowel, keeps the trunk immutably bent forwards. In cases of artificial anus, the end of this cord, corresponding to the intestine, is attached to the bottom of its angle on the side towards the belly, precisely at the base of the *éperon* interposed between the two orifices. Hence the *éperon*, and the bowel terminating at it, must be continually drawn towards the cavity of the abdomen by the mesentery: and thus we may discern how the motion and posture of the trunk backward should have a favourable influence in promoting a spontaneous cure. Sometimes, however, the tension of the mesenteric cord ruptures the adhesions of the ends of the bowel to the parietes of the abdomen, and causes a fatal effusion of intestinal matter within the peritoneum. Long after the spontaneous cure of an artificial anus, the effect of this action of the mesentery may be to separate the bowel completely from the parietes of the abdomen,

and restore it to its free and floating condition again. Dupuytren ascertained this fact by *post mortem* examinations; a fact, which he would have had difficulty in crediting, if he had not been perfectly certain of the identity of the individuals, and had not detected in each of them a fibrous cord extending from the point of the parietes of the abdomen, corresponding to the former artificial anus, to the bowel. (See *Clinique Chir.* t. ii. p. 206.)

It is then in the deeper part of the funnel-shaped tube, which, as we have seen, lies between the opening in the skin and the bottom of the artificial anus, that the most remarkable and important dispositions of an artificial anus are placed. Here are situated the orifices of the two ends of the intestinal canal, and the septum between them. Of these two orifices, one belongs to the upper part of the bowel; and, being always pervaded by alimentary matter, or *fæces*, is the freer and larger; the other is continuous with the lower portion of the bowel; and since it transmits no alimentary nor *fæcal* matter, or only trivial quantities, it is usually narrow, contracted, and not readily detected.

[The intermediate funnel-shaped cavity, described by Scarpa, being formed by the remains of the hernial sac, is of course only met with in those cases of artificial anus which result from strangulated hernia. When the affection is produced in any other way, there is no cavity of this kind, and consequently, the two orifices of the bowel and the projecting septum are then much nearer the surface, and the contents pass more directly from the upper orifice at once out at the wound. The presence of the intermediate cavity is, in many instances, of great utility in promoting a spontaneous cure; for if the intestinal matters, after they have passed from the upper portion of the bowel into this cavity, can re-enter its lower portion more readily than they can escape by the fistulous opening on the surface, the latter may gradually contract and close, and a natural cure be effected. In such a case the lost portion of intestine is in fact replaced by the remains of the hernial sac. It may be stated, therefore, that, *cæteris paribus*, there is a greater probability of the intestinal matters resuming their natural course without surgical interference, in artificial anus from hernia, than in artificial anus from other causes.]

Desault, after noticing the efficiency of the adhesions, between the injured part of the bowel and the edge of the opening in the parietes of the abdomen, in preventing extravasation, remarks, that if such adhesions were entire, the abdominal parietes would form a substitute for the portion of the canal which has been destroyed, and the contents of the bowel would continue to pass, as usual, towards the anus, were it not that the portions of the intestine separated and adherent to the neighbouring parts, form such an acute angle as obstructs the passage of the intestinal matter. The more acute this angle is, the greater is the obstruction; when the two parts of the bowel lie nearly parallel, the entrance into the lower portion of the canal is completely prevented; but if they meet at a right angle, then more or less of the contents of the upper portion may be transmitted into the lower. The first disposition chiefly happens when a considerable part of the intestinal canal has been destroyed, or when the tube has been completely divided; while the second is principally remarked in cases where the injury has been less ex-

tensive. And it is plain that the possibility of a cure depends materially on the kind of angle at which the two portions of bowel meet, and that the projection of the internal frænum, or jutting membranous ridge between the two orifices, is always a greater or lesser obstacle to the cure.

With respect to the diminution which occurs in the diameter of the part of the intestinal canal, between the artificial opening and the natural anus, Desault admits the correctness of the observation, but entirely dissents from such authors as have spoken of the change as sometimes proceeding so far that an obliteration of that portion of the intestinal tube is the consequence. The mucus secreted within it suffices for preventing this obliteration; a secretion which, in these cases, is copious, and is partly voided from the rectum in the form of white flakes. And, if any further proof were needed that the bowels between the artificial and natural anus remain pervious, it is furnished by the fact, that, in cases of artificial anus, the lower continuation of the tube frequently becomes inverted, and protrudes. On the other hand, the kind of obliteration above spoken of has never been demonstrated by dissection: it was not observed by Lecat, in the examination of the body of a person, who died twelve years after the entire cessation of the passage of *fæces per anum*; nor was it found to exist by Desault, when he opened a patient who died of marasmus in the Hôtel Dieu, in consequence of an artificial anus, which communicated with the ileum, and had lasted two years. (*Œuvr. de Desault*, t. ii. p. 354—356.)

It is true, then, that the lower portion of the intestinal canal undergoes a kind of atrophy, but, perhaps, is never obliterated or rendered quite impervious. Such atrophy, according to Dupuytren, extends to the corresponding part of the mesentery and mesenteric glands; and after some years, such is the difference between the upper and lower parts of the intestinal tube, that while the former seems to be that of an adult, the other looks as if it belonged to a new-born infant. (*Clinique Chir.* t. ii. p. 210.)

I believe the only case, forming an exception to the assertion of Desault, that the lower portion of the intestinal canal is never obliterated, is that met with by M. Bégin, in the Val de Grace. It was that of a man, eighty years of age, who, for forty years before he died, had been afflicted with artificial anus, communicating with the transverse arch of the colon. The intestine below the artificial anus was transformed into a solid cord, not larger than a quill, until it approached the anus, when its diameter increased, and its solidity lessened. Here it contained also a whitish mucus; and in other parts was only capable of admitting a small probe, except for the space of six or eight inches towards the artificial anus, where its cavity was totally obliterated. (See *Dict. de Méd. et de Chir. Pratiques*, t. iii. p. 133.)

However proper the formation of an artificial anus may be in many cases in which the patient's life depends upon the event, it must be confessed that the consequence is a most afflicting and disgusting infirmity. This truth cannot be denied, though the *fæces* which are discharged, from not having been so long retained in the bowels, may not be so fetid as those which are evacuated in the ordinary way. As the opening which gives vent to the excrement, is not endowed with the same

organisation as the lower end of the rectum, and as, in particular, it is not furnished with any sphincter capable of contracting and relaxing itself, as occasion requires, the *fæces* are continually escaping without any knowledge of the circumstance on the part of the patient. Hence the uncleanly state of the parts around the external opening, and their frequently excoriated fungous state. Some persons in this state, among the number of those whose histories are on record, made use of a metal box, in which their excrement was received. Schenckius relates the case of an officer who was wounded in the belly, and who allowed his *fæces* to escape into a vessel made for the purpose. Dionis mentions a similar case. Moscati also communicated to the Academy of Surgery the history of a wounded man, in whom an artificial anus took place in consequence of a wound in the abdomen below the right hypochondrium. His excrement used to be received in a tin box, fastened to him with a belt. The wound received a leaden canula, to which the tin box was accommodated.

Uncleanliness is not the only inconvenience of an artificial anus. Persons have been known to be quite debilitated by the affliction, and even ultimately to die in consequence of it. This is liable to happen, whenever the intestinal canal is opened very high up, so that the aliment escapes before chylification is completed, and the nutritious part of the food has been taken up by the lacteals. In this circumstance the patient becomes emaciated and sometimes perishes, as Desault had an opportunity of observing; and examples of which are also on record by Hoin and Le Blanc. In cases of this description, the matter voided has little *fœtor*, and is frequently sourish. In all instances, the matter is evacuated involuntarily, because there is nothing like a sphincter. But when the opening only communicates with the lower convolutions of the ileum, or, what is more frequent, with the large intestines, the danger is less serious, and patients in this state are often noticed performing all their functions very well; and, with the exception of colic, to which they are subject, enjoying as good health as they did previously to their having the present disease. In such examples, the matter voided is more fetid, its discharge does not follow so quickly its introduction into the stomach, and it is retained for a longer time.

On this part of the subject, the investigations of Dupuytren led to some interesting information, which was, that the upper or stomachic portion of the intestinal canal not only preserves its calibre, motion, and natural appearance, but, in consequence of having an increased duty to perform, it acquires an increase of capacity, and becomes the seat of a more energetic circulation, as well as of more active secretion and absorption. This excess of life, says he, is propagated even to the mesentery and its glands.

In cases of artificial anus, the regular convolution of the bowels, so favourable for the advance of their contents, are immediately affected at some point or another. A noose of intestine is elongated, and drawn towards the breach in the parietes of the abdomen; it assumes the form of a triangle, the base of which is the mesentery, while one side is the stomachic portion, the other the anal continuation of the intestine. In every simple hernia,

we see the difficulty occasioned to the free course of the intestinal matter, by the deviation of the bowel from its regular and uniform curve, and its assuming an angular direction. Besides, as Dupuytren has admirably explained, the bowel being, in cases of artificial anus, fixed by adhesions to the parietes of the abdomen, this state not only resists the motions of the digestive tube, but it makes the adherent portion of the bowel a fixed point, towards which all the efforts of the intestinal canal are concentrated, and towards which its contents are incessantly directed: whence a true acceleration of them from the stomach to the artificial anus. A still more serious inconvenience is the shortening of the track which they have to pass. Their lodgment in the intestinal canal being abridged, their digestion remains incomplete, and the absorption of their nutritive principles is performed with less precision. Then nutrition is impaired, and the exhaustion threatens to render the continuance of all the organic functions impossible. (See Dupuytren, *Clinique Chir.* t. ii. p. 213.)

Many patients, afflicted with an artificial anus, void no fæces at all from the rectum; but, occasionally, a thick whitish substance, which is the mucous secretion of the portion of the large intestines nearest to the anus. Under certain circumstances, the quantity of this mucous discharge is more copious. (*Desault*, vol. cit. p. 359.)

Another disagreeable occurrence, to which persons with an artificial anus are exposed, is a prolapsus of the bowel, similar to what sometimes happens through the anus with respect to the rectum. The descent of the bowel is sometimes simple, only affecting a portion of the intestinal canal just above, or below, the opening. On other occasions, the complaint is double, the bowel both above and below the opening being prolapsed. This descent of the intestine forms a tumor, the dimensions of which vary considerably in different subjects. Instances have been known of its attaining the length of sixteen or eighteen inches, or even two feet. (Dupuytren, *Clinique Chir.* t. ii. p. 200.) The surface of the prolapsus is reddish, like that of the inside of the intestine, though discoloured by the irritation of exposure to the air. When it has been of long continuance, the mucous membrane becomes dense and solid, covered with a thin dry cuticle, and assumes the characters of cutaneous texture. (See Dupuytren, vol. cit.) When the protrusion is caused by the upper part of the intestinal canal, the fæces are voided at the extremity of the tumor; and when the swelling consists of the lower portion of the bowel, the excrement is evacuated at the base of the prolapsed part. By observing this evacuation, when the tumor is double, it is easy to know to which end of the intestinal canal each protruded portion belongs. This consequence of an artificial anus is very serious, because it greatly increases the inconvenience which the patient suffers. Sometimes the tumor is exquisitely sensitive; and, occasionally, when the eversion of the intestine is considerable, a strangulation is produced, which puts the patient's life in danger.

An artificial anus, particularly that formed by the destruction of the whole calibre of the bowel, rarely continues a simple fistulous opening, but almost always becomes complicated with a prolapsus of the intestine, the interior of which becomes everted as well as protruded. This happens with

greater facility, in proportion as the intestine is less fixed in the cavity of the abdomen. The protrusion is more considerable, in proportion as the efforts of the patient at stool are greater; and it is the more afflicting, the older the artificial anus is. The prolapsus, or protrusion of the lower end of the bowel, is less common than that of the upper; it is not so voluminous; and seems to be occasioned by the antiperistaltic movements which propel the mucous secretion of the lower part of the intestinal canal towards the artificial anus. (See Dupuytren, *Clinique Chir.* t. ii. p. 199.) These tumors are usually of an elongated conical shape, with the apex in the integuments, and a depressed aperture in the base, whence is discharged stercoraceous matter, if the prolapsus be connected with the upper portion of the bowel; and mucus, or even the fluid of clysters, if connected with the lower.

The following interesting case of artificial anus, complicated with prolapsus, is recorded by Mr. Lawrence.

"The patient, sixty years of age, has voided all his stools through the groin for about seventeen years, and still retains the external appearances of health and activity. His complaint was a scrotal hernia of the size of a pigeon's egg, before the occurrence of the strangulation which ended in mortification. The testis of the same side, and a large portion of the surrounding integuments, were involved in destruction with the hernia. He had never worn a truss, nor taken any measures to obviate the inconveniences arising from the discharge of his fæces, except that of keeping always a quantity of tow in his breeches."

"A prolapsus of the intestine has taken place through the artificial opening. The projecting part varies in length and size at different times. It was four inches long when I saw it; and the basis, which is the largest part, measured nearly six inches in circumference. This prolapsus never recedes entirely, but is sometimes considerably smaller. It has occasionally protruded to the length of eight or ten inches, being at the same time equal in size to the forearm, and bleeding copiously. This is attended with great pain, and only happens when the bowels are much disordered. Warm fomentations and a recumbent position relieve in this case, by causing the gut to return."

"The prolapsus is of a uniform red colour, similar to that of florid and healthy granulations. The surface, although wrinkled and irregular, is smooth and lubricated by a mucous secretion. It feels firm and fleshy, and can be squeezed and handled without exciting pain: it approaches on the whole to a cylindrical form, and its anterior loose extremity, which is of circular figure, contains a roundish depressed opening, through which the stools are voided. The basis of the swelling is continuous on all sides with the integuments, and I could discover no opening of the lower end of the gut. This person does not possess the slightest power of holding the stools. They are often voided suddenly and without giving him any notice. When the fæces are fluid, which is generally the case, they come away repeatedly in the day, and are discharged with considerable force; but when they are of a more firm consistence, there is not more than one stool in two or three days, and their expulsion requires much straining. At these times their size is not greater than the little finger."

"Whenever he retains his urine, after feeling

an inclination to void it, a quantity of clear inoffensive mucus, like the white of an egg, amounting to about four ounces, is expelled from the anus; and this may occur two or three times in the day."

"When he is purged, the food frequently passes with little alteration; this he has noticed particularly of cucumber. He experiences great weakness at such times. Ale will sometimes pass off in five minutes from the time of drinking, having apparently undergone little or no alteration. The bowels are strongly affected by slight doses of purgatives." (*Treatise on Hernia*, 5th ed. p. 416.)

Should the protruded intestine become strangulated, an operation may be necessary for the removal of the stricture. (*Schmucker, Vermischte Chirurgische Schriften*, t. ii.) Two cases, which terminated fatally from this cause, are mentioned by Sabatier, in a memoir in the 5th tome de l'Acad. de Chir. Mr. Lawrence also refers to Le Blanc. (*Précis d'Opérations de Chir.* tom. ii. p. 445.) We should always endeavour to prevent such protrusions, when a disposition to their formation seems to exist, by the use of a steel truss, which should, indeed, be worn by the patient, independently of this circumstance. If the tumor has become irreducible by the hand, an attempt may be made to replace it by keeping up a constant pressure on the part, the patient being at the same time confined to bed. (*Lawrence*, op. cit. p. 421.)

By these means, Desault returned a very large prolapsus; and by pressure on the opening, the feces were made to pass entirely by the anus, although for four years they had been voided only through the wound. (*Parisian Journ.* vol. i. p. 178.)

In cases of artificial anus, the appearance of the mucous coat of the bowel undergoes some change, in consequence of exposure to the air on the contact of extraneous bodies; it becomes redder and less villous; but does not cease to secrete a great quantity of mucus: this is one of the principal reasons why it is so difficult to close the fistulous opening, even when the passage for the feces has been restored. The skin around an artificial anus is also generally very irritable, and rendered exceedingly painful by the contact of the excrement. (*Breschet*, in *Graefe's Journ.* b. ii. p. 303.)

With respect to the prognosis, it is universally agreed, that *cæteris paribus*, an artificial anus is more dangerous the nearer it is to the stomach, for reasons already explained. An opening produced by injuries of the cæcum, colon, or rectum, has scarcely any effect on that part of the digestive function termed assimilation. The risk is also in some measure greater, in proportion as the quantity of intestinal matter voided from it is more considerable. The prognosis is more favourable, when the two orifices of the bowel are readily found at the bottom of the artificial anus, than when only the orifice of the upper end is discoverable. Lastly, the more free an artificial anus is from complications and accidental ill consequences, the less is the patient the subject of annoyance and danger. (See *Dupuytren, Clin. Chir.* t. ii. p. 223.)

Treatment.—The treatment of an artificial anus is either palliative or radical. The first consists in obviating the habitual uncleanness produced by the involuntary discharge of the intestinal matter, and in relieving any unpleasant symptoms present.

The first indication is fulfilled by the employ-

ment of silver, or tin machines, which are either kept applied to the external opening by means of a spring, or form receptacles placed more or less distant from the artificial anus, from which the intestinal matter is transmitted through a tube, kept constantly in the opening. In general, says Desault, as elastic gum is supple, light, and capable of taking any shape, it is the best material for the construction of such instruments, which, however, rarely answer their purpose completely.

An instrument of this kind, the construction of which appears very perfect, is delineated by Juville. (*Traité des Band. Herniaires*, sect. viii. pl. vii. and viii.) An ordinary inguinal truss is made with an ivory pad, perforated in its middle, so as to fit the opening. A tube of elastic gum, furnished with a valve opening downwards, leads from this perforation to a receiver of silver, which is attached by a screw to the lower end of the tube, and lies against the inside of the thigh. The silver vessel may be unscrewed and emptied without disturbing the rest of the instrument. It has been found, in some instances, that a common elastic truss, with a compress of lint under the pad, has been more serviceable than any complicated instrument in preventing the continual flow of feculent matter from the artificial opening. (*Treatise on Hernia*, 5th ed. p. 388.)

Richter, with the view of hindering the too quick escape of the intestinal matter, and the death of the patient from this cause, proposed covering the opening for a certain time with a piece of sponge, supported by an elastic bandage, or truss. But Loeffler found this method objectionable, as it was apt to bring on colic, constipation, and an inflamed excoriated state of the skin.

When the outer opening is disposed to contract too much, and *inconveniences arise from this change*, Sabatier is an advocate for preventing such closure by means of a tent, or skein of silk, introduced into the aperture, and changed very often for the sake of cleanliness; while others prefer a ring of ivory for the purpose. But the irritation produced by the matter imbibed by this sort of tent, and in particular the liability of the bowel to protrude, and be strangulated in the opening of the ivory ring, are found strong objections to these practices. Desault preferred a linen tent, compress, and bandage.

The investigations of Scarpa and Dupuytren fully prove, that the causes of the discharge of the intestinal matters through an artificial anus, and the obstacles to their resuming their natural course, and to a radical cure, depend,—1st, Upon the adhesion, angular direction, and fixed condition of the bowel. 2nd, Upon the loss of substance which it has sustained, and the consequent contraction of it. 3rd, Upon the jutting angle (*éperon*) and the double septum between its two orifices. These obstacles, great as they may be, are sometimes overcome by nature and art. Loss of substance is indeed irreparable; but amends for it may be made in certain cases by a dilatation of the calibre of the bowel. Its adhesion to the parietes of the abdomen may also become less close, or even so loosened as to let the bowel assume a position and direction more favourable for the re-establishment of the course of its contents. The projection, formed by the *éperon* and double septum, may also be lessened by being continually dragged by the mesentery, and subjected

to the effort of the intestinal matter to get from the upper into the lower portion of the bowel. A rich full diet is recommended by M. Louis, for the purpose of gradually enlarging the communication between the two portions of bowel: purgatives, administered with the view of forcing the obstacles to a free communication; the introduction of tents, the size of which is gradually increased, in order to dilate the contraction between the two parts of the intestine; the movement and position of the trunk backward, advised by Dupuytren to render the mesentery tense, and to efface the projecting angle and the septum continued from it; compression of the external opening, practised from time immemorial, to hinder the intestinal contents from escaping outwards, and obliging them to pass by the natural way, — are all, as Dupuytren observes, so many resources, which, employed singly or unitedly, have accomplished many cures. (See *Clinique Chir.* t. ii. p. 225.)

But everybody must agree with this distinguished practitioner, that, previously to attempting to cure the principal disease, all accidental complications should be removed; as an indurated or inflamed state of the skin, extensive sinuses, or a prolapsus of the intestine. The latter, according to Dupuytren, is easily obviated by keeping the patient a few days on his back, and having recourse to the taxis with gentleness, and moderate steady compression. Almost all artificial ani, attended with a simple perforation of some point of the circumference of the bowel, are set down by Dupuytren as curable. These cases are in reality but stercoraceous fistulæ, behind which the intestinal canal is almost entire, without loss of substance, or any manifest contraction, or material change of direction. Here nature is disposed to close the accidental opening, and her efforts, assisted by moderate compression, are mostly successful. But Dupuytren explains that this simple treatment will not answer when the artificial anus has been produced by the destruction of a third or a half of the circumference of the bowel, for an extent varying from a few lines to an inch. Yet here, the loss of substance, the changed direction of the intestine, and the jutting angle between the two portions of it, are not so considerable as to prevent the restoration of the natural passage for the intestinal matter from being brought about by suitable treatment. Nay, he adds, that cases are not absolutely incurable by the plans above adverted to, even when the artificial anus was the consequence of a loss of substance, involving two-thirds or three-quarters of the circumference of the bowel, with a proportionate length of it. But when the loss of the substance amounts to four-fifths, or the whole of the circumference, with or without the inclusion of a piece of the mesentery, such methods will not avail. Here the diminished calibre of the bowel, its altered direction, the jutting angle, and the double septum, present themselves in the strongest manner as invincible impediments to the re-establishment of the natural course of the alimentary matter; and, as Dupuytren further remarks, pressure, which, when made with precision, is the most effectual means of closing the outlet, immediately brings on colic, nausea, hic-cough, vomiting, and all the symptoms of strangulated hernia.

When, therefore, the whole, or the greater part, of the stools is discharged by an artificial anus

no attempt must be made to stop up the opening, without a great deal of consideration; for any effort of this kind, made under circumstances which do not justify it, may be the means of exposing the patient's life to the most alarming danger. Sometimes, indeed, without any interference of the surgeon, the outward opening contracts, and, the issue of the intestinal matter being obstructed, pain and tenesmus are excited; and the same consequences may be produced by any swelling and enlargement of the projecting ridge situated between the two portions of the bowel. In two cases, Puy found this swelling take place in such a degree, that the patients fell victims to the complete stoppage of the intestinal contents. The symptoms which arise are then similar to those which happen in strangulated hernia. Hoin, Le Blanc, and Sabatier, also cite instances, in which the patients lost their lives by gangrene, brought on by this species of strangulation. (*Desault*, vol. cit. p. 360.)

There is a period (says Mr. Travers) at which the function of the lower portion of the canal, with a little assistance, may be restored. The natural order of events, connected with this recovery, has been mistaken and inverted. Practitioners have closed the wound, instead of conducting the matter by purgatives and clysters into the large intestines. Now, the wound will never fail to heal, when the matter recovers its accustomed route; but this condition cannot be reversed. The restoration is safest when most gradual; when there is evidence of an existing sympathy between the repair of structure and the return of function. According to the same gentleman, there is reason to believe that the well-timed exhibition of a single purgative might often prove effectual. "If the food is rapid, and little changed in its passage, it should be pul-taceous and nutritive, and given in moderate quantity at short intervals; while injections of the same kind should be administered at least twice in twenty-four hours, and retained as long as possible." He states, that by such means patients may be nourished for many weeks. If the discharge is sparing, and does not readily escape, he recommends an occasional purgative in less than ordinary quantity. He disapproves of other medicines, especially stimulants, and all such food as is difficult of digestion, giving a general preference to animal food in a gelatinous form. He bestows just praise on strict attention to cleanliness; and, in opposition to Desault and Sabatier, condemns the employment of tents and sponges. (*Op. cit.* p. 371, 373.)

Numerous cases on record furnish abundance of proofs that the fæces, after being voided for several months from the wound produced by the operation for hernia, frequently resume their natural course. Facts of this kind, which, in general, may be said to be common when the intestine is without loss of substance, are not very rare even when more or less of the bowel has been destroyed by gangrene; and many illustrations of this remark may be found in the writings of De la Peyronie, Louis, Petit, Pott, Le Dran, &c. Several such cases have fallen under my own observation. The greater number of these instances of success, as already stated, were the result of the most simple unofficial treatment, or rather of the undisturbed and very little assisted efforts of nature.

[In an excellent article in the *Cyclopædia of*

Practical Surgery, by Mr. T. P. Teale, headed *Intestinal Fistula*, this statement is fully corroborated. Mr. Teale gives a table exhibiting eleven cases, taken indiscriminately, in which the fæculent discharge following gangrenous hernia spontaneously ceased. In eight of these cases, the time when the cessation occurred is specified, and is found to vary from thirteen to seventy days; or on the average to be thirty-nine days. The quantity of intestine destroyed is not in all the cases noted; but in some of them the gangrene must have implicated a few inches of the tube; and in an instance related by Scarpa, a long loop of intestine was lost. (*Cyclop. of Pract. Surg.* vol. ii. p. 194.)

Mr. Teale gives further tables, showing thirteen cases of penetrating wounds of the abdomen, attended by fæcal discharge, only two of which were followed by permanent intestinal fistulæ; the remaining eleven closed spontaneously: also ten cases of gun-shot injury of the intestine, in eight of which a perfect cure took place without interference. The remaining two were followed by permanent fistulæ, but in each of these the loss of substance was considerable, and in consequence of the absence of the membranous funnel, formed by the sac in cases of mortified hernia and the retraction of the divided extremities of the intestine which this structure has been shown to promote, the natural powers of nature were inadequate to restore the continuity of the canal. Both these cases, however, were cured by the introduction of linen tents, after the manner of Desault, which will be next referred to.]

According to Desault, the most frequent impediment to the restoration of the natural course of the intestinal contents, is the angle formed by the two portions of the intestine; and, says he, it must be enlarged, and rendered less acute, in order that the fæces may continue their route. This desirable change he recommends to be effected by introducing long dossils of charpie into the two ends of the bowel, and gradually altering their direction so as to bring it into a straight line. When the dilatation is sufficient, and the inner angle, or ridge, is effaced, the long dossils need not be continued. The linen tent, with the precaution of not introducing it too deeply, lest it obstruct the course of the fæces, will then suffice. When this plan is skilfully managed, Desault says, there will be a great chance of its succeeding, and its beneficial effect will be denoted by a rumbling in the bowels, and frequently by slight colics. At first, wind is discharged from the rectum, and, soon afterwards, the fæces begin to come away. On the contrary, if they should not pass with facility, the colic be violent, and an accumulation happen in the upper portion of the intestinal canal, the tent must be withdrawn, and any other cause of obstruction be considered, and, if possible, removed. (Vol. cit. p. 365, &c.)

[By this method Desault succeeded perfectly in a very unpromising case, which has been already alluded to, accompanied by a prolapsus nine inches in length, although no fæces had passed per anum for more than four years. After four days he succeeded in returning the prolapsus; the linen tent was then introduced, and in a few hours fluid fæcal matter passed by the rectum. The evacuations were very numerous during the night and for the three following days;

but they gradually became thicker and diminished in number. The linen tent was discontinued on the eighth day, and the opening was closed by lint and compresses supported by a truss with a broad and flat pad. This plan entirely prevented the escape of fæcal matter by the wound. The fistulous opening remained, but a very trivial serous exudation could scarcely be said to stain a small piece of lint placed upon it. (*Œuvr. Chir.* tom. ii. p. 370, and *Parisian Journ.* vol. i. p. 178, also quoted at length by Lawrence, 5th ed. p. 390. For a somewhat similar case from Scarpa, see also Lawrence, p. 422).]

From a calculation made by Dupuytren, it appears that artificial ani, capable of spontaneous cure, or of one produced by the means already specified, are, in comparison with the examples which obstinately resist such treatment, as three to one. (See *Clin. Chir.* t. ii. p. 223, 229.) It was for these latter cases that Dupuytren devised a method of cure which reflected upon him the highest credit, and which I shall now proceed to describe.

In the preceding columns, I have given a full explanation of the impediment made to the passage of the fæces into the lower orifice of the intestinal canal, by the projecting septum, or ridge between the two parts of the bowel, and the matter having sometimes to traverse the funnel-shaped membranous cavity in quite a semicircular track. A representation of this septum may be seen in Scarpa's work, tab. 9, fig. 1; and in the sixth plate of Mr. Travers's Inquiry. (See also *Bourgery, Med. Opér.* tom. ii. pl. 33.) In one example in which this septum was plainly visible in the wound, Dupuytren introduced into the orifice of the upper part of the bowel a curved needle; and, passing it through the projecting septum, brought it out again through the orifice of the lower portion of the gut. Thus, he included a considerable part of the septum in a ligature, which was daily made tighter, with a view of first exciting inflammation in the two layers of this septum, and thus ensuring their adhesion together; and his next plan consisted in making a division through the part embraced by the ligature, whereby the passage for the fæces into the lower portion of the bowel was made quite free. But, as the section made by the ligature was too superficial, Dupuytren completed the division of the septum with a knife; but peritonitis and the death of the patient ensued. According to Dr. Breschet, the ligature also proved ineffectual; because its operation was so slow, that adhesions and cicatrization took place behind it as fast as it made its way through the rest of the septum. Hence, the expectation that the fæces would sufficiently pass through the aperture made by the ligature was not realised; and in one case quoted by Breschet, though some amendment followed the operation, still the cure was far from being accomplished, as only some of the fæces passed out of the natural anus, while the remaining and greater part of them still came through the fistula. (See *Graefe's Journ.* b. ii. p. 300; also *Clinique Chir.* t. ii. p. 233.) In another case Dupuytren tried to render the layers of the septum adherent by compressing them between the blades of a pair of forceps of particular construction; and afterwards he effected the division of the part by augmenting the compression, by means of a screw traversing the handles of the

instrument. In a case which followed the operation for bubonocoele attended with mortification of the bowel, Dupuytren began with dilating the outer opening with a bistoury; and after ascertaining the position of the septum between the two orifices of the bowel, he introduced one of the blades of the forceps into each portion of the gut, and closed the instrument with the screw. The part of the instrument situated externally to the ridge, or septum, he covered with charpie and a compress. The constriction was soon followed by colic pains, and tendency to vomit, complaints which were quickly removed by fomenting the belly. They recurred, however, the instrument became loose, and some discharge ensued. On examination, the septum was found to be partially divided. After the breadth of the instrument had been lessened it was applied again; but when the screw was turned the patient began to suffer such violent pain over the whole of the abdomen, that it was necessary to diminish the pressure; and as the instrument was afterwards separated from the parts in a fit of vomiting it was withdrawn. A trial was now made to determine the fæces towards the rectum by pressure on the external opening; but the plan could not be endured, and the hindrance to the egress of the intestinal matter was so oppressive that it was discontinued. As the forceps used on the foregoing occasion did not take sufficient hold of the septum, nor divide it properly, the instrument was somewhat altered. A particular description of its improved make has been inserted by Breschet in *Graefe's Journal*, b. ii. p. 302; and likewise in t. ii. of *Dupuytren's Clinique Chir.* p. 248, where it is termed *enterotome*. Dr. Reisinger published three cases in which it was successfully employed by Dupuytren. In the first of these examples, when the instrument had been applied, it embraced the septum so well, that it could not be displaced from it. The colic attacks, vomiting, thirst, furred tongue, and loss of appetite, which ensued, soon gave way after the belly had been fomented; the constriction was then increased, and found to produce less and less indisposition. After a few days very little of the fæces came out of the artificial anus; and five natural evacuations took place. The blades of the instrument were now completely closed, and on taking it out a slough of membrane was found between the blades; a proof that the septum was destroyed. On the next day the patient's health was undisturbed. Clysters were now administered, with the view of promoting evacuations in the natural manner; and the next day the patient had a proper motion, without any assistance, and a very small quantity of the fæces passed out of the fistulous opening. This aperture was now merely covered with charpie; but, as some high granulations were rising, the powder of colophonium was sprinkled upon them, and compresses and a bandage were applied. The use of clysters was also daily continued, though the patient voided his fæces in the natural way. On discontinuing the external pressure, the quantity of discharge from the fistulous opening increased; and, therefore, on the 1st of October, the compresses were again applied, and kept on the part with a spring truss. The treatment ended in a perfect cure.

In another case, Dupuytren enlarged the lower angle of the outer opening with a bistoury; and

after feeling with his finger that both orifices of the bowel were close to that opening, he applied the forceps. In the evening, the constriction was increased, which was followed by severe colic pains over the whole abdomen. They subsided, however, the following day. From the outer opening, a great deal of slimy excrement was discharged. The constriction was not augmented. On the fifth day, the patient was attacked in the night with pain and vomiting. The following night he was also very restless. Though the belly was not tense, it could not bear to be touched. On the eleventh and twelfth days, the patient was free from pain; and, by means of clysters, two natural motions were procured; and on the fourteenth, as the patient was easy, Dupuytren began to make pressure on the fistulous opening. On the twenty-sixth, the edges of the aperture were touched with lunar caustic; and on the twenty-eighth a compress supported by a spring truss was applied. The patient was kept constantly in the horizontal posture; the fæces began to be voided the natural way regularly, and the opening contracted in the most favourable manner.

I think the generality of surgeons will agree with Dr. Reisinger, that the foregoing treatment cannot be indiscriminately adopted, in all descriptions of patients, without danger. It should never be tried too soon after the formation of an artificial anus; but time should be allowed for the irritability and sensibility of the gut, and especially of the septum, to be lessened by the effect of the air and the pressure of the fæces. Nor should the trial ever be made ere it has been fully ascertained that nature cannot herself bring about the cure. Breschet mentions an example, in which the foregoing method could not have been practised, in consequence of the mouth of the lower portion of the bowel having been obliterated by the pressure of a large tent, three inches long, which had been worn by the patient two years, and the projecting ridge could not be detected. (See *Graefe's Journ. de Chir.* b. ii. p. 298.) Many other interesting observations on this proposal may be perused in the memoir by Dr. Breschet, in Dr. Reisinger's tract, the title of which is given in the list of works at the end of the present article, and in *Dupuytren's Leçons Orales*, &c. t. ii. In order not to incur the risk of extravasation of the fæces in the abdomen, the constriction of the septum should never be increased with imprudent haste, before the adhesive inflammation has had time to be produced between the two layers, of which that part is composed.

The following general directions were given by Dupuytren for the management of these cases:—
1. The two ends of the bowel must be detected.
2. The septum between them divided. 3. The external opening healed up.

The lower end of the intestine he frequently found very difficult to make out. In old cases, very often neither the angle (*éperon*), nor the lower portion of the bowel, can be discovered; and it seems as if there was only one passage, leading to the fistula. The other, partly obliterated, and retracted within the belly, has an orifice so concealed, that, unless accidentally entered by a probe, its detection is almost impossible. Then the relation of the two portions of intestines to one another, Dupuytren found remarkably inconstant. The stomachic portion, according to

the kind of case, may be superior or inferior, external or internal. When the artificial anus communicates with the great intestine, he considers clysters amongst the best means of discovering the orifice of the lower continuation of the intestinal canal. In very difficult cases, he sanctions the use of a plug, purgative clysters, and a very full diet. (See *Clinique Chir.* t. ii. p. 265.)

The two ends of the bowel being ascertained, the operation must not be performed if the mucous coat of the bowels, the peritoneum, or other organs be the seat of acute or chronic inflammation. The patient is to be prepared by a suitable, mild, antiphlogistic plan.

In the operation the patient is to lie upon his back. The surgeon takes one of the branches of the *enterotome* in the right hand, and guides it, if requisite, with the left forefinger, to one of the orifices of the bowel, to the depth of one, two, three, or four inches, according to circumstances. An assistant then takes charge of this first part of the instrument. The other branch is then introduced into the other end of the bowel in the same manner. Both branches are then brought together, and joined like a pair of forceps. The blades are then made to grasp the bowel by pressing the handles together. The pressure is next regulated and maintained by means of a screw. Before the expiration of the first day, the pressure is to be increased sufficiently to kill the portion of intestinal tunics embraced by the instrument; and the pressure is to be again augmented every second day, to render its destruction still more certain. In the cases under Dupuytren, the instrument was detached between the seventh and tenth day, bringing away with it the destroyed jutting angle and septum, which prevented the upper portion of bowel from communicating with the lower. Frequently the first signs of the re-establishment of the natural passage precede the detachment of the enterotome. In all cases, slight colic occurs, the evacuations are at first white and albuminous from the lower bowels, and these are followed by stercoraceous matter from the upper ones. At first they are numerous and liquid, and attended with gripings; but they soon become of proper quality, and all uneasiness subsides. (See *Dupuytren*, in *Clin. Chir.* t. ii. p. 264, &c.)

If, after the destruction of the septum, and the re-establishment of a free communication between the two portions of the bowel, the external fistula were not to admit of being healed by pressure and other ordinary means, no doubt could be entertained of the propriety of resorting to the plan of attempting to cure it by paring off the edges and bringing them together with sutures, as was sometimes done by Dupuytren; or on Taliacotian principles, as successfully exemplified by Mr. G. F. Collier. (See *Med. and Physical Journ. for June*, 1820.) Dupuytren, for the purpose of making the sides of the fistula remain in contact, or making them approach each other, occasionally applied an ingenious little instrument, consisting of two pads, which, by means of a screw, can be made to embrace the part. An engraving of it may be seen in *Graefe's Journ.* b. iii. taf. 3, fig. 9. For the closure of the fistula, Dupuytren also sometimes had recourse to a truss, and now and then to the actual cautery.

If after the contraction, or perfect closure of the external opening, the patient should be attacked

with colic, nausea, vomiting, and other symptoms of retention of the intestinal matter; and these complaints were not to yield to diluent drinks, aperient injections, and fomentations, Dupuytren recommends making a prompt incision through the cicatrix, and forming a free outlet for the matter accumulated above it. (See *Clinique Chir.* t. ii. p. 272.)

[Several modifications of the enterotome have been devised, the object of which has been to give to the new communication a more circular form, instead of being a mere longitudinal fissure, as is the case when Dupuytren's instrument is used. Liotard contrived an instrument to remove a portion of the septum in shape like the segment of a circle, and this has been advantageously modified by Bourgery for its more easy introduction into the bowel. (See *Bourgery, Op. Surg.* vol. ii. pl. 33, and *Teale*, op cit. p. 210.) It is doubtful however, whether any material advantage is thus obtained, since the opening made by the original instrument has always been found sufficient for the passage of the feces, and probably after a time always becomes of a more or less circular form, as it was found to be in one of Dupuytren's cases, which was examined by Lallemand seven years after the operation.

The following is Dupuytren's statement of the results of this operation: "Forty-one operations have been performed, twenty-one by myself, and twenty by other practitioners. The bowel had mortified from strangulation in three-fourths of the cases; in the other fourth there had been wounds with loss of substance. Three cases terminated fatally; one from supposed fecal effusion into the abdomen; another from indigestion; the third from the peritonitis excited by the operation. Of the remaining thirty-eight, the greater number had no unpleasant symptoms; some indeed had colic, nausea, and vomiting, but these symptoms yielded to drinks containing carbonic acid, to leeches round the anus and fomentations of the abdomen."

"The cure was not equally complete in all. Fistulae, more or less extensive, remained in nine, rendering the constant use of a truss necessary, in order to prevent the involuntary escape of air, mucus, bile and even fecal matters. Twenty-nine patients were completely and radically cured in periods varying from two to six months." (*Mem. de l'Acad. Royale de Méd.* tome i. and *Lawrence*, op. cit. p. 411.)

Mr. Lawrence remarks: "cases of artificial anus must be much more common in Paris than in London. Dupuytren employed his method in between twenty and thirty instances within a short time. No opportunity has occurred to me of putting it into practice either at St. Bartholomew's Hospital or elsewhere, for several years; and I believe that it has hardly been employed at all in this country." It appears from the observations of M. Jobert, that the representations of Dupuytren respecting the mild nature and successful results of his operation should be received with some allowance. He states that in the cases observed by him, very serious inflammatory symptoms resulted from the application of the enterotome. He adds that a patient in the Hôtel Dieu of Amiens, died of entero peritonitis after its application, and that several other fatal cases have been recorded. (*Traité des Mal. Chir. du Canal Intest.* tome ii. p. 125.) M. Velpeau adverts to the risk that the adhesive inflammation may not always take place

at the periphery of the enterotome, even after it has been applied in the most judicious manner; also, that in some cases it is impossible not to include between the branches of the instrument a portion of some important organ at the same time with the abnormal septum. (*Op. Surg.* Mott's transl. vol. ii. p. 632.)

A very ingenious instrument has been contrived by Mr. Trant of Dublin, to effect a cure on Desault's principles, *i. e.* to restore the canal by pressing back the septum, but without the division or removal of any portion of it. One part of the instrument is made to press back the *éperon* towards the spine, while another part retains the anterior wall of the intestine in close contact with the posterior surface of the abdominal parietes, by which the danger of separating the delicate adhesions in this situation is prevented, which might otherwise cause a fatal extravasation into the cavity of the abdomen. (See *Dublin Med. Press*, 1845, p. 305.) (James R. Lane.)

Professor Delpech invented forceps which first took hold of the septum, between the two portions of the bowel, and then divided it by means of two little knives, which, on touching a spring, glided along the interior of the blades, and met towards their end. A representation of it may be seen in *Froriep's* 268th plate, fig. 4. The plan of cutting the septum, however, is abandoned, as likely to cause effusion of the contents of the intestinal canal, and peritonitis. *Lallemant*, in *Répertoire Gén. d'Anat.* &c. rédigé, par G. AORTA. *ἀορτή*, the principal systemic artery. Aneurisms of this vessel have already been treated of: but some other particulars relating to it merit notice in a dictionary of surgery.

WOUNDS OF THE AORTA.

[The general opinion of surgeons is that wounds of this vessel are necessarily and instantly fatal. If the wound be of a size to permit the escape rapidly of a large quantity of blood, this result would of course be inevitable. Cases are recorded

however in which patients have survived small punctured wounds of the aorta for weeks, or even months. In one case related by Guattani the patient recovered from the wound, a false aneurism, however, followed at the point of puncture, as discovered by a post-mortem examination several years afterwards. In the *Journ. de Med.* t. xlv. p. 435, a case is described where a patient was wounded in the aorta just at its origin from the left ventricle, and where death followed on the sixth day. Another case is recorded by Lerouge, in which the wound passed through the right auricle and the aorta, notwithstanding which the patient lived till the eleventh day. (*Recueil d'Observations Chirurgicales de Saviard.*)]

The following case is recorded by M. Pelletan. In the month of May, 1802, a young man was brought to the Hôtel Dieu. In a duel, he had been run through with a foil, which penetrated above the right nipple, and came out at the left side of the chest. The most alarming symptoms were apprehended; but several days elapsed without any serious complaints taking place. The patient was bled twice, and kept on a very low regimen. Everything went on quietly for a fortnight. He now complained of severe pains in his loins, and he was relieved by the warm bath. He seemed to be recovering, got up, and went to walk in the garden allotted for the sick; but the pain in his loins quickly returned, attended with difficulty of breathing, constipation, and wakefulness. He now became very impatient, and out of temper with the surgeons for not relieving him. On the 15th of July, two months after the accident, a deformity of the spine was remarked, about the eighth dorsal vertebra. The patient grew rapidly worse, and died in the utmost agony, saying that he felt suffocated; and tearing off his shirt that his chest might be free from the pressure of all kind of clothing. On the body being opened, the right side of the chest was found full of blood, coagulated in various degrees; and an opening, the diameter of which was equal to that of a writing pen, was detected in the aorta above the crura of the diaphragm. All the adjacent cellular substance was injected with blood, and three of the dorsal vertebræ were found carious. No mark of injury was perceptible in any of the thoracic or abdominal viscera. (*Pelletan, Clinique Chir.* t. i. p. 92—94.)

THICKENING AND CONSTRICTION OF THE AORTA.

Meckel met with two cases in which the aorta was thickened and considerably constricted, just below its arch; yet, in both subjects, there was every reason to believe that the abdominal viscera and lower extremities had been duly supplied with blood. This fluid, which could only pass from the heart with great difficulty, and in small quantities, had, by regurgitating, lacerated the semilunar valves. (*Mém. de l'Acad. Royale de Berlin*, 1756, Obs. 17 and 18.) A similar example is recorded by Stoerk. (*Ann. Méd.* xi. p. 171.) An instance, in which a stricture was met with in the aorta, opposite to the termination of the ductus arteriosus, is described by Sir Astley Cooper. The little finger could hardly pass through the constriction, which impeded the course of the blood through the heart and lungs, and was attended with a considerable dilatation of the right ventricle. (*Surgical Essays*, vol. i. p. 103, 8vo. Lond. 1818. For other facts of this kind, see *Bertin et Bouil-*

land, *Traité des Mal. du Cœur et des Gros Vaisseaux*; Reynaud, in *Journ. Hebdom. de Méd.* t. i. &c.) Gangræna senilis is sometimes connected with disease and morbid deposits within the aorta. (See *Carswell's Illustrations of the Elem. Forms of Dis.* fasc. 7, pl. 3, fig. 2.) See MORTIFICATION.

OBLITERATION OF THE CAVITY OF THE AORTA.

It is observed by Professor Scarpa, that the whole body may be regarded as an anastomosis of vessels, a vascular circle; and he contends that this remark is so true, that even an obliteration of the aorta itself, immediately below its arch, may take place, without the general circulation of the blood in the body being stopped. Such a disease of the aorta was seen by M. Paris in the body of a woman. While she lived, the blood, which was expelled from the heart, was transmitted into the trunk of the aorta, below the constriction; and it got there by passing, through the subclavian, axillary, and cervical arteries, into the mammary, intercostal, diaphragmatic, and epigastric arteries. From these latter arteries, the blood passed into the vessels of the thoracic and abdominal viscera, and into those of the lower extremities. (See *Desault, Journal*, t. ii. p. 107; *Brasdor*, in *Recueil Périodique de la Soc. de Méd.* t. iii. No. 18.) Another instance of complete obstruction of the aorta was met with by Monro. (See *Obs. on Aneur. of Aorta*, p. 5.) Dr. Graham, of Glasgow, published another example, in which the aorta was completely obstructed just below the canalis arteriosus. (See *Med. Chir. Trans.* vol. v. p. 287.)

Dr. Goodison, of Wicklow, in examining the dead body of a woman, in the Hospice de la Pitié at Paris, and endeavouring to trace the origin of the inferior mesenteric artery, discovered a hard tumor placed upon the aorta, and accompanied with an obliteration of that vessel from the origin of the inferior mesenteric artery downwards the remainder of its length; the left iliac being also rendered impervious down to its bifurcation, and the right for more than one half of its length. The corpora sesamoida of the semilunar valves of the aorta were considerably enlarged, and the mitral and tricuspid valves presented the appearances termed by Corvisart "vegetations." The arch of the aorta was greatly enlarged, and internally was studded with patches of bone. The vessels given off from the aorta, and especially the lumbar arteries, were all noticed to be considerably increased in size. At the obliterated part of the abdominal aorta, there was a firm bony sheath, covering the vessel for about two inches, and filled with a hard fleshy substance, which extended further upwards, and was firmly adherent to the coat of the artery. It was the inner coat itself which was ossified. For a particular account of the vessels which were chiefly enlarged for the purpose of continuing the circulation, I must refer to Dr. Goodison's description. The general appearance of the body was not unhealthy; and the lower extremities, which were not emaciated, must have been well supplied with blood. The history of the case could not be traced. Mr. Crampton, having carefully compared Dr. Goodison's narrative with the preparation taken from this subject, refers the obliteration of the aorta to the effects of the process by which an aneurism had been spontaneously cured; in which particular, this case is quite different from those reported by M. Paris

and Dr. Graham. (See *Dublin Hospital Reports*, vol. ii. p. 193, &c. 8vo. 1813.)

The foregoing cases proved that the obliteration of the canal of the aorta, at any one part, is not incompatible with the continuance of life; and suggested the possibility of the application of a ligature to it being the means of sometimes saving the patient from the doom of certain death.

The next case which I shall notice, is one of the most memorable in the annals of surgery, since it was nothing less than an operation in which a ligature was applied, for the first time, to the aorta of a living subject, under circumstances which, at a time when the successful repetition of Brasdor's operation had not been made (see *Wardrop, On Aneurism*, 1829), perhaps warranted even this desperate attempt to preserve life. Sir Astley Cooper had often placed ligatures round the aorta in dogs, and found that the blood was readily carried by the anastomoses to their posterior extremities (see *Med. Chir. Trans.* vol. ii. p. 158); and he came to the conclusion, that if the aortic plexus be tied with the artery, the lower extremities are rendered paralytic, and the animal ultimately dies; but if care be taken to include only the vessel in the ligature, these consequences do not take place. (See *Lancet*, vol. ii. p. 47.)

A porter, aged thirty-eight, was admitted into Guy's Hospital, April 9, 1817, for an aneurism in the left groin, situated partly above, and partly below, Poupart's ligament. The swelling was considerably diffused, and pressure upon it gave a great deal of pain. On the third day from his entrance into the hospital, the tumor increased to double its former size, and the pulsation became less distinct. The blood could be felt in a fluid state within the sac, which was so large that no operation was practicable without opening the peritoneum. Sir Astley Cooper therefore waited, in order to let the man have a chance of a spontaneous cure. Notwithstanding the practice of venesection and compression, the swelling continued to increase, and on the 20th of June a bleeding took place from a point of the tumor where a slough had formed. The bleeding recurred from time to time; and on the 25th he was so much exhausted by loss of blood that his feces passed involuntarily, and his immediate death was only prevented by pressure on the opening. At nine o'clock in the evening, this experienced surgeon made a small incision into the sac above Poupart's ligament, and introducing his finger tried if it were practicable to pass a ligature round the external iliac artery within the cavity; but the thing was found impossible, as, instead of the vessel, "only a chaos of broken coagula" could be perceived. At the moment of withdrawing the finger, two students compressed the aorta against the spine, and the incision was then closed with a dossil of lint. Sir A. Cooper now determined to apply a ligature to the aorta itself. "I made (says he) an incision, three inches long, into the linea alba, giving it a slight curve to avoid the umbilicus. One inch and a half was above, and the remainder below the navel," the cut being inclined towards the left side. "Having divided the linea alba, I made a small aperture into the peritoneum, and introduced my finger into the abdomen; and then with a probe-pointed bistoury, enlarged the opening in the peritoneum to nearly the same extent as that of the external wound. Neither the omen-

tum nor the intestines protruded; and during the progress of the operation, only one small convolution projected beyond the wound." With his finger-nail he scratched through the peritoneum, on the left side of the aorta; and then gently moving his finger from side to side, he gradually passed it between the aorta and spine, and again penetrated the peritoneum on the right side of the aorta. A blunt aneurismal needle, armed with a single ligature, was next conveyed under that vessel; care was required in tying the ligature to exclude the intestines from the noose. The wound was then closed by means of the quilled suture and adhesive plaster. During the operation, the fæces were discharged involuntarily, and the pulse, both immediately and for an hour after the operation, was 144. An opiate was given, and the involuntary passage of fæces soon ceased. The sensibility of the right leg was very imperfect. In the night the patient complained of heat in the abdomen; but he felt no pain upon pressure; and the lower extremities, which had been cold a little while after the operation, were regaining their heat, but their sensibility was very indistinct. At six o'clock the following morning, the sensibility of the limbs was still imperfect; but at eight o'clock the right one was warmer than the left, and its sensibility returning. At noon, the temperature of the right limb was ninety-four; that of the left, or aneurismal one, eighty-seven and a half. At three o'clock, an enema was ordered. The heat of the right leg was now ninety-six; that of the left or diseased limb eighty-seven and a half. It is unnecessary here to detail all the various circumstances which preceded the patient's death. Vomiting, pain in the abdomen and loins, involuntary discharge of urine and fæces, a weak pulse, cold sweats, &c., were some of the most remarkable symptoms. At eight o'clock on the second morning after the operation, the aneurismal limb appeared livid and cold, more particularly round the aneurism; but the right leg was warm; and between one and two o'clock the same day, the patient died. On opening the abdomen, there was not the least appearance of peritoneal inflammation except at the edges of the wound; and the omentum and intestines were of their natural colour. The ligature, which included no portion of intestine or omentum, was placed round the aorta, about three quarters of an inch above its bifurcation. When the vessel was opened, a clot, of more than an inch in extent, filled it above the ligature; and below the bifurcation another clot, an inch in extent, occupied the right iliac artery, while the left contained a third, which extended as far as the aneurism. The neck of the thigh-bone was also found broken within the capsular ligament, and not united; an accidental complication. As there were no appearances of inflammation of the viscera, Sir Astley Cooper refers the cause of the man's death to the want of circulation in the aneurismal limb, which never recovered its natural heat, nor any degree of sensibility, though the right leg was not prevented from doing so; hence, says this experienced surgeon, "in an aneurism similarly situated, the ligature must be applied before the swelling has acquired any very considerable magnitude." (*Surgical Essays*, vol. i. p. 114, &c.)

Indeed, the most important conclusions from this case are:—First, that where no other impediments exist, the circulation will continue in

the lower extremities, though the abdominal aorta be tied, or suddenly obstructed. Secondly, that suffering aneurismal swellings to become very large, before the operation is done, exposes the patient to considerable disadvantage, on account of the pressure of the disease upon the surrounding anastomoses, whereby the continuance of the circulation is rendered less certain than it would be were the operation done at an earlier period.

Sir Astley Cooper mentions, that if he were to perform the operation again, he would cut off the two portions of the ligature close to the knot on the vessel; because the irritation of the bowels by them seems to him a source of considerable danger. He has also said, that if a case like the foregoing should again occur to him, he would seek the aorta behind the peritoneum. (See *Guthrie, On Dis. of the Arteries*, p. 363.) Whoever has practised the operation of tying the common iliac artery on the dead subject must be fully aware of the practicableness of this last method: in my friend Mr. James's case, however, which I am about to notice, he found the peritoneum so firmly adherent to the aneurismal sac that he says that it would have been absolutely impossible to have detached them from one another; and the method of operating, therefore, without opening the peritoneum, could not have been followed. (*James, in Med. Chir. Trans.* vol. xvi. p. 15.) In a third example, however, of ligature of the aorta, when Dr. Murray was the operator, the latter plan was executed, "without more difficulty than was to be anticipated." The patient died twenty-three hours after the operation. (See *Lond. Med. Gaz.* for 1833, 1834, p. 68.)

[Mr. James's case was one of aneurism of the external iliac artery, situated too high to allow of a ligature being applied to that vessel above the tumor. Brasdor's operation was consequently first performed—the ligature was applied to the common femoral artery, half an inch below its origin. This operation failed, however, to arrest the progress of the aneurism. After an interval of three weeks, it was therefore decided, on consultation, to tie the aorta itself.] Mr. James began the external incision an inch above the umbilicus, and extended it down to two inches below it. After the peritoneum had been opened, great embarrassment was occasioned by the protrusion of the distended bowels. The handle of the aneurism-needle broke at the moment the instrument was passed under the aorta. "The broken part was so sharp," says Mr. James, "that I was obliged to withdraw it for fear of injuring the intestines. With some additional difficulty I got my finger, with Weiss's instrument upon it, under the artery; but, even after this had been effected, it was by no means easy, with the best assistance of my colleagues, to extricate the short needle bearing the ligature, so much did the intestines interfere with every kind of manipulation. When the ligature was underneath, I kept the intestines out of the way with the fingers of both my hands, and placed one of my thumbs on the vessel, whilst Mr. Luscombe drew it (the ligature) first on my thumb, and then on the artery." The tumor immediately became flaccid, and a deadness in the lower extremities was complained of. We shall only add, that the patient afterwards suffered severe pain in the lower limbs, which never ceased till he died, which event took place three hours and a

half after the operation. During this short time, the temperature of the lower limbs was equal to that of the trunk; but it fell in every part of the body. The particulars of the post mortem examination are interesting; but I can only state here, with reference to Brasdor's operation, that "the external iliac artery did not terminate in the femoral, as usual, but gave off two trunks of nearly equal size; and from the inner, which corresponded with the profunda, the epigastric was given off." Mr. James does not regard then the result of his attempt as unfavourable to Brasdor's method; "for a considerable and satisfactory alteration was produced by tying only one of the trunks which led from the iliac, and had the distribution been natural, it is not improbable," says he, "a cure would have been obtained." (See *Med. Chir. Trans.* vol. xvi. p. 14.)

On this subject I find the following observations made by my friend Mr. Crosse:—"I meet yearly with recorded instances of a portion of the aorta being entirely obliterated, and the accounts of such cases are often followed by a word of encouragement to repeat the application of a ligature to this vessel. Astley Cooper, James, and Murray, are the only names associated with this undertaking; and its intrepid originator allows me to say, that he would not repeat the operation, except under an improved and a more safe plan of conducting it; approaching to the sentiments of a recent writer, who sums up a full consideration of the subject by remarking that *the operation ought not to be again performed.*" (Crosse, in *Prov. Med. and Surg. Trans.* vol. v.) I am disposed to be of this opinion myself; and, at all events, believe with Mr. Guthrie, that the ligature of the aorta may be in almost every instance superseded by that of the common iliac artery. I think also with him, that if the operation ever succeed, it will be when the aorta is taken up by passing the finger under the peritoneum, along the common iliac artery, up to that vessel. (See *Guthrie*, op. cit. p. 372.)

[Since the above was written, two additional cases of ligature of the abdominal aorta have been published, making five altogether. The fourth case occurred in the practice of Dr. C. B. Monteiro, at Rio Janeiro. The case was one of false diffused aneurism of the femoral artery, forming a large swelling situated in the lower part of the abdominal cavity, on the right side. The operation was performed Aug. 5th, 1842. The ligature was applied behind the peritoneum, two lines above the bifurcation of the aorta. The patient died on the tenth day after the operation of secondary hæmorrhage, arising from a small opening in the aorta immediately above the ligature. (*South, Translation of Chelius*, p. 255.) The last and fifth case on record was under the care of Mr. South, in St. Thomas's Hospital. This was for an aneurism of the false and diffused kind, affecting the common iliac artery, in a robust young man, aged twenty-eight. The tumor was large, occupying the right side of the abdomen, extending from the iliac fossa to near the cartilages of the ribs. The operation was performed on the 21st of June, 1856. An incision was made on the left side from a little above the anterior superior spinous process of the ilium, to just below the cartilage of the tenth rib. The peritoneum was raised from the lateral and posterior wall of the abdomen, and a ligature was passed around the aorta from right to left, just

above the bifurcation. The patient survived the operation forty-three hours. (*Lancet*, for July 12th and Aug. 23rd, 1856.)

The peritoneal cavity has been so frequently and extensively opened of late years, in the operation for the removal of ovarian cysts, that the opinions of surgeons with regard to abdominal surgery in general, and more especially in reference to the risks attending wounds of the peritoneum have been materially modified. It has been abundantly shown, that the danger of such wounds, when intentionally made by the surgeon with clean cutting instruments and without bruise or violence to the contained viscera, has been over estimated. With this knowledge before him the surgeon of the present day should, it appears to me, give the preference to Sir Astley Cooper's method of cutting directly through the peritoneum to expose the aorta, if called upon to apply a ligature to that vessel.

The danger attending this formidable operation, judging from the cases on record, does not appear to arise so much from the wound of the peritoneum as from the want of adequate circulation in the lower extremities, especially on the side of the aneurismal swelling. This latter cause of failure may fortunately, in future operations, to a great extent, be provided against, *by applying the ligature above instead of below the giving off of the inferior mesenteric artery*: by this proceeding a stream of blood corresponding to the size of the anastomosing branch of the middle and right colic arteries would be available for the supply of the lower limbs. The amount of blood entering the aorta by the inferior mesenteric artery through the channel above indicated, would appear to be a suitable quantity for the purpose of ensuring the required circulation, without distending the aneurismal sac so as to endanger its rupture.

From the above considerations, I am not altogether opposed to the performance of this operation where it offers the only chance of life, nor should I be greatly surprised to hear that a successful case of ligature of the aorta in the human subject had been added to the triumphs of operative surgery.]

RUPTURE OF THE AORTA WITHIN THE PERICARDIUM.

The surgical writings of Scarpa, in relation to the formation of aneurisms, have now gained extensive celebrity in the world. It is well known that this author maintains the doctrine, that, in all aneurisms, the internal and muscular coats of the artery are ruptured; and that the aneurismal sac is not formed of these tunics, but of the dilated cellular sheath which surrounds the vessel. When a large aneurism bursts, there is always a double rupture; one of the artery, another of the aneurismal sac. The last is that which is the immediate cause of the patient's destruction, by altering the *circumscribed* state of the aneurism into the *diffused*.

There are some exceptions, however to the foregoing statement; and Scarpa has not failed to point them out. When the internal and muscular coats of the aorta are ruptured in a situation where the outside of the vessel is only covered by a thin, tense, closely adherent membrane, such membrane may be ruptured at the same time with the proper coats of the artery, and sudden death be occasioned by the effusion of blood in the cavity of the thorax. These events are liable to happen whenever the proper coats of the aorta are ruptured

within the pericardium, where the vessel is only covered by a thin layer reflected from this membranous bag. Walther has recorded one example of this kind, and Morgagni several others. A similar case is related by Scarpa. Several specimens are contained in the museums of the London Hospitals. (See *Haller, Disput. Chir.* tome v.; *Acta Medic. Berlin*, vol. viii. p. 86; *Morgagni De Sed. et Causis Morb.* Epist. xxvi. art. 7, 17, 21; Epist. xxvii. art. 28; *Scarpa, On Aneurism, transl. by Wishart*, p. 81. Also *Hodgson, On the Diseases of Arteries and Veins.*)

STEATOMATOUS TUMORS OF THE AORTA.

Two steatomatous tumors were noticed by Stenzel in the body of a male subject. They were situated in the substance of the membranes of the aorta, immediately below its arch. Notwithstanding these swellings had rendered the vessel almost impervious, the man had the appearance of strength, and of having been well nourished. *Hæc corpora fere cor magnitudine æquabant ut omnem propemodum exeunti e sinistri cordis thalamo sanguini spatium præcluderent.* De Steatomatibus in principio arteriæ aortæ, &c. Wittemb. 1723. This is another striking fact, illustrating the great power of the inosculation to carry on the circulation.

COMPRESSION OF THE AORTA,

In order to restrain hæmorrhage from the inferior half of the body, more especially from the uterus, has been warmly advocated, and in thin persons seems calculated to be beneficial. (See *Crosse, Provincial Med. and Surgical Trans.* vol. v.) I have mentioned the adoption of this plan by Sir Astley Cooper, in the case where he opened the aneurismal sac, previously to putting a ligature on the aorta.

APHÆRĒSIS (from ἀφαίρεω, to remove). A term formerly used in the schools of surgery to signify that part of surgery which relates to the removal of any portion of the body.

APONEUROSIS. Matter often collects under aponeuroses, particularly under those which cover the muscles of the thigh, leg, and forearm. Abscesses are also sometimes met with under the temporal, the palmar, and the plantar fasciæ; in the tendinous thecæ, which include the flexor tendons of the fingers; and, occasionally, also in the aponeurotic sheath, in which the rectus abdominis muscle is situated.

One particular effect of an aponeurosis, or fascia, lying between a collection of matter and the skin, is materially to retard the progress of the pus towards the surface of the body. Hence, if the case be allowed to take its own course, the quantity of matter increases; the pus spreads extensively under the aponeurosis in every possible direction; separates the muscles from such fascia, and the muscles from each other; and the abscess does not burst till a vast deal of mischief has been produced, together with more or less sloughing of the fascia, tendons, &c. These circumstances cannot happen without a considerable degree of constitutional disturbance, and a permanent loss of the use of certain muscles. Even when a spontaneous opening is formed, and some of the matter escapes, it is often only a very imperfect discharge; for the aperture generally occurs, not in a depending situation, nor over the main collection of pus, but at a part where the aponeurosis is thinnest, and consequently where the matter has the least resistance to overcome in getting to the surface of the body.

In all such cases, the chief indication is to make an early and a depending opening with a lancet, so as to prevent the extension of the abscess, and to let the matter escape as fast as it is formed. If a spontaneous opening should have occurred in an unfavourable place, a new aperture must be made in a proper situation, or if the former should be sufficiently depending and near the principal accumulation of matter, but too small, it must be rendered larger with a curved bistoury and a director. Whenever any black dead pieces of fascia, or tendons, present themselves at the opening, they must be taken hold of with a pair of forceps, and extracted.

APPARATUS MINOR; APPARATUS MAJOR; APPARATUS ALTUS. Three ways of cutting for the stone. (See **LITHOTOMY.**)

AQUA PICIS LIQUIDÆ. *Dubl.* Take of tar two pints; water a gallon. Mix them with a wooden rod for a quarter of an hour, and after the tar has subsided, let the liquor be strained, and kept in well-corked bottles. This lotion is often used in porrigo, and ulcers surrounded with scorbutic redness.

ARCHOPTOSIS. See **RECTUM, PROLAPSUS OF.**

ARGENTI NITRAS. (*Nitrate of Silver, lunar caustic.*) See **SILVER, NITRATE OF.**

[**ARNICA.** The tincture of the flowers of this plant has been thought to be efficacious in promoting absorption in bruises, sprains, and extravasations of blood. A lotion composed of two ounces of tincture of arnica to eight ounces of water may be employed for this purpose. Mr. Erichsen "entertains no doubt of its efficacy." He states that he has employed it largely in extensive extravasations, and has rapidly promoted their absorption by its use. (See *Science and Art of Surg.* p. 83.)]

ARSENIC was the chief ingredient in a secret remedy, which long obtained celebrity in Ireland for the cure of cancer, and is now well known amongst surgeons by the name of Plunket's caustic. This application consists of the ranunculus acris, the greater crowfoot, the flammula vulgaris, and the lesser crowfoot, in the proportion of an ounce of each, bruised and mixed with a drachm of the white oxide of arsenic, and five scruples of sulphur. The whole is to be beaten into a paste, formed into balls, and dried in the sun. When required for use, these balls are beaten up with yolk of egg, and spread upon a piece of pig's bladder. The use of the ranunculus is to destroy the cuticle, upon which the arsenic would have no effect; for it is to be observed that Plunket's caustic was employed for the dispersion of tumors as well as for the relief of ulcerated cancers. The application is to remain on the part twenty-four hours, at the end of which the slough is to be dressed with any simple unirritating ointment. When arsenic was first recommended as an application for cancer, it used generally to be blended with opium. When Plunket's caustic is employed, so as to form an eschar over a scirrhus tumor, I conjecture that if it ever do good, it is not by any specific effect of this arsenical application, but simply by its producing a slough. It is highly probable also that the swellings which have been thus dispersed, have never been complicated with the structure characteristic of true scirrhus. With respect to cancerous ulcers, Plunket's caustic sometimes produces a degree of amendment, which,

however, rarely lasts for any considerable time ; but many inveterate ulcerations and anomalous sores derive permanent benefit from it, and are even completely cured by it. Some examples of lupus, ulcerations about the roots of the nails, and reputed carcinomatous sores of the lips, are of this description.

At Paris, an arsenical paste was formerly used by Dubois, and other surgeons of that capital, for cancerous sores of the penis, and other malignant ulcers. It was composed of seventy parts of cinabar, twenty-two of sanguis draconis, and eight of the white oxide of arsenic (arsenious acid), formed into paste with saliva at the time when it is to be employed. "The pain and inflammation that succeed the use of it (says Mr. Crosse) cannot be equalled by the severest operations with the knife. (*Sketches of the Medical Schools of Paris*, p. 45, 8vo. 1815.) Even death may be occasioned by the absorption of the poison, as appears from the two annexed facts, the first of which is recorded by M. Roux, in his *Médecine Opératoire*. "The day after the paste was applied, the patient complained of colic and severe vomiting, and in two days perished in convulsions, *et les plus vives angoisses*. The internal coat of the stomach, and a great part of the intestinal canal were inflamed, and marked here and there with dark spots." Just before I visited Paris (adds Mr. Crosse), I dissected in London a woman who died under similar circumstances, and where the same morbid appearances were presented, &c. (Op. cit.)

Justamond's applications to cancer were generally combinations of arsenic and sulphur. One formula was an ounce of yellow arsenic, with half that quantity of armenian bole, and sometimes as much red precipitate. He also employed a sulphuret of arsenic, and a combination of this sulphuret with crude antimony. The arsenical preparation selected for use was scraped, and laid on the middle of the sore, the edges of which were moistened with a combination of the muriate of iron and muriate of ammonia. In some instances, it is alleged the effects of the treatment were the correction of the fetid smell, melioration of the appearance of the sore, and separation of the cancerous part.

In the *Pharmacopœia Chirurgica*, Justamond's arsenical caustic is directed to be made in the following manner:—℞. Antimonii pulverizati, ℥j. Arsenici pulverizati, ℥ij. These are to be melted together in a crucible. The application may be reduced to any degree of mildness by blending with this pulverised caustic a quantity of opium in the form of powder, which was also supposed to act specifically in diminishing pain.

The powder of white oxide of arsenic, unmixed with other substances, has sometimes been sprinkled upon cancerous and other inveterate ulcers ; but the practice is now abandoned by every judicious surgeon, on account of the violent pain resulting from it, and the not unfrequently fatal consequences of its absorption. Could I suppose that a man so rash and ignorant as to revive this murderous practice yet existed in the profession, I should feel disposed to lengthen these remarks ; but I am persuaded that, in this country at least, more judgment and knowledge everywhere prevail. The white oxide of arsenic, however, may be applied with more prudence in other forms ; either in one of those already specified ; or as a

lotion, composed of eight grains of the oxide, and the same quantity of subcarbonate of potash, dissolved in four ounces of distilled water ; or as an ointment, formed by rubbing together one drachm of the oxide, and twelve drachms of spermaceti ointment. (See *A. T. Thomson's Dispensatory*, p. 51.)

In the American edition of this Dictionary, Dr. Reese observes : "There can be little doubt that *arsenic* is the basis of the active ingredients of most of the popular nostrums of the day, which are set forth in our public papers as infallible remedies for the cure of cancerous affections, as they are termed ; and hence the manifold evils which we often witness from such practice. So long ago as in 1786, Dr. Rush favoured the public with an exposition of the nature of the famous cancerous powder of Dr. Martin ; its base was arsenic ; though, like the specifics of our own time, it was alleged to be of a vegetable nature. The external application of arsenic ought to be had recourse to only after the severest scrutiny into the peculiar character of the case and constitution affected. Even in small quantities it has produced apoplexy, mental aberration, organic lesion of the stomach, paralysis, loss of motion, enlargement of the joints, fatal petechiæ, &c. Arsenic, in fact, may be enumerated among that class of poisons which induces nearly the same effects when externally applied as when taken inwardly. The experiments of Brodie, as well as those of other philosophers, demonstrate that its influence on the system is no less rapid and dangerous when had recourse to as an external application to denuded surfaces than when applied directly to the stomach. Another peculiarity of its action deserves also farther to be stated : according to Professor Francis (*Lectures on Forensic Medicine*), in some cases, even while favourable anticipations from the operation of this powerful agent locally applied are indulged, of a sudden the general health yields, and death ensues rapidly and unexpectedly ; an occurrence of much consideration in the investigations of the juridical physician."

Febure's celebrated remedy consisted of ten grains of the white oxide of arsenic, dissolved in a pint of distilled water, to which were then added an ounce of the extractum conii, three ounces of the liquor plumbi subacetatis, and a drachm of laudanum. With this fluid the cancer was washed every morning. Febure likewise gave arsenic internally ; and his prescription was two grains of the white oxide ; a pint of distilled water ; syrup of chicory, q. s. ; and half an ounce of rhubarb. Of this mixture, a table spoonful was given every night and morning, with half a drachm of the syrup of poppies. Each dose contained about one-twelfth of a grain of arsenic ; but, in proportion as the patient was able to bear an increased quantity, the dose was gradually augmented to six table spoonfuls of the solution.

Dupuytren was in the habit of employing certain preparations of arsenic, which cleaned the diseased surfaces without destroying them. One of his formulæ was a powder ; the other a liquid. The arsenious acid constituted the basis of both. The calomel, joined with it, he conceived might have some effect ; but the arsenic was the essential thing. The powder consisted of four parts of arsenious acid, or oxide of arsenic, and ninety-six of calomel. Sometimes the proportion of

arsenic was increased to five or six parts in the hundred. The liquid preparation was principally the above powder mixed with gum arabic, and moistened with distilled water, so as to make a paste. In the latter formula, however, Dupuytren usually increased the proportion of arsenic, employing six, eight, ten, or twelve parts of arsenic, with so many parts of calomel as made, with the arsenic, one hundred. Dupuytren employed this application with considerable success for the cure of many phagedenic ulcerations of the lips, and other parts of the face, approaching almost to cancer in respect to obstinacy. (See *Clinique Chir.* t. iv. p. 471.) In University College Hospital, I employed Dupuytren's arsenical powder last year, in one or two instances of the same kind, with complete success. In lupus, or noli-me-tangere, it is a valuable application.

[In onychia maligna, Mr. Luke speaks highly of an ointment containing two grains of arsenious acid to an ounce of spermaceti ointment.]

The liquor potassæ arsenitis (Ph. Lond.), or Fowler's solution, is the formula commonly employed for the internal exhibition of this mineral. A fluid ounce of this solution contains four grains of arsenious acid. The dose, according to Dr. Fowler, is as follows:—From two years old to four, M. ij or iij to v; from five to seven, M. v to vij; from eight to twelve, M. vij to x; from thirteen to eighteen, M. x to xii; from eighteen upwards, M. xii. These doses may be repeated every eight or twelve hours, the medicine being diluted with thick gruel, or barley-water. [Dr. Pereira remarks, that the quantities here indicated are larger than it will be safe, in most cases, to commence with. Half an ounce, taken in the space of five days, is supposed to have caused death. (*Elem. of Mat. Med.* 3rd ed. vol. i. p. 669.) For an adult, about five minims is now the ordinary dose; ten minims would be considered as an excessive quantity by most practitioners. As the preparation is decomposed by the infusion and decoction of cinchona, it should never be ordered with either of these medicines. It should be taken immediately after a meal, when the stomach is filled with food; for when given on an empty stomach it is much more likely to occasion gastric disturbance.

The iodide of arsenic has been recommended by Dr. Walshe in the treatment of scirrhus tumors of the breast. It should be given in doses of a sixteenth to a twelfth of a grain twice daily, and may be continued without risk for several months. He thinks he has observed that under its use the pain decreases in violence, and that the active growth of the tumor may be diminished, and perhaps suspended. (See *Treatise on Cancer*, p. 202, Lond. 1846.)]

It will only be in my power to specify here a few of the numerous surgical cases in which the internal employment of arsenic has been proposed. The following are particularly worthy of attention: cancer; lupus; elephantiasis; onychia; various unnamed malignant ulcers; various cutaneous affections, lepra, psoriasis, eczema, &c. A longer list of diseases, for which a trial of arsenic is suggested, may be seen in some papers published by Mr. Hill. (*Edin. Med. and Surg. Journ.* vols. v. vi.)

In cases of poison by arsenious acid, or arsenite of potash, practitioners universally agree respecting the first indication; which is, to empty the stomach

as quickly as possible, with the stomach pump or an emetic. In this country, if the pump be not at hand, the common practice is to exhibit an emetic of sulphate of zinc, or sulphate of copper, which (it is said) ought to be preferred; first, because it does not require much dilution for its action—a circumstance of no small importance where poisons act by being absorbed; and, secondly, because it is extremely expeditious, a dose of fifteen or twenty grains producing almost instantaneous vomiting, without exciting that previous stage of nausea, which so frequently characterises other emetics, and which produces a state of the vascular system highly favourable to the function of absorption. (See *Pharmacologia* by Dr. Paris, p. 232, vol. i. ed. 5.) If the pump be used, Dr. A. T. Thomson is of opinion that lime-water should be used to wash out the stomach. The union of lime and arsenious acid forms a nearly insoluble salt; so that while we are freeing the stomach from its deleterious contents, we are also lessening the virulence of any part of it which may remain. If the above emetics be given, lime-water should be drunk immediately after the first act of vomiting. Oil, and also milk, may be given; but no diluent fluid calculated to dilute and dissolve the arsenious acid. Alkaline solutions are objectionable, because the alkaline arsenites are very soluble, and as poisonous as arsenic itself. (See *Thomson's Elements of Therapeutics and Materia Med.* p. 518, ed. 2.)

It is remarked by Orfila, that lime-water offers no particular advantage in cases of poison with the solid arsenical acid; but, where this acid is fluid, he admits the great utility of lime-water, as, in this circumstance, an insoluble arsenite of lime is formed, the action of which is very weak. This last observation is confirmed by experiments on dogs. (*Toxicologie Générale*, t. i. p. 233, ed. 2.)

When inflammation of the abdomen, and alarming nervous symptoms prevail, the means of relief are leeches, venesection, the warm bath, fomentations, emollient clysters, and antispasmodic narcotic medicines.

Success will depend, in a great measure, upon the regimen observed during the patient's convalescence: he should be chiefly nourished with milk-gruel, cream, rice, and beverages of a mucilaginous nature. (See *Orfila*, t. cit. p. 235.)

In 1831, the hydrated sesquioxide of iron was discovered, by Dr. Bunsen, to be a powerful antidote, if administered in time. (See *J. G. Crosse*, in *Prov. Med. Trans.* vol. v. p. 51; *J. Robson*, in *Lond. Med. Gaz.* Nov. 5. 1836.)

[If a sufficiently large quantity of the hydrated sesquioxide be added to a solution of arsenious acid, it combines with the acid, and forms an insoluble precipitate. Dr. Maclagan says that twelve, Devergie thirty-two, parts of the hydrated oxide are required for every part of arsenious acid swallowed. Dr. Beck recommends that it should be given in the quantity of a table spoonful every five or ten minutes, or as often as the patient can swallow it. But it appears from the experiments of Dr. A. Taylor, that when the hydrated sesquioxide is mixed with arsenious acid in the form of powder, that little or no chemical effect is produced. Now, as in most cases of arsenical poisoning, the arsenious acid is taken in the form of powder, it follows that in such the hydrated sesquioxide would not act as an antidote. Nevertheless, according to Dr. Beck, the results of its employ-

ment have been encouraging. In thirty-one cases in which it was given recovery took place in twenty-nine. In one of these, nearly two drachms of arsenic had been taken. In the two unsuccessful cases, the antidote could not be retained on the stomach. (See *Pereira, Elem. of Mat. Med.* 3rd ed. vol. i. p. 767.)]

ARTERIES. The process, by which a divided or punctured artery is healed, is particularly considered under the word **HÆMORRHAGE**; while the general principles, which ought to be observed in the application of the means for the stoppage of bleeding, may be collected partly from the remarks contained in that part of the work, and partly from what is stated in the articles **AMPUTATION**, **ANEURISM**, and **LIGATURE**.

As the condition of a bleeding patient admits of no delay, and the preservation of his life entirely depends upon proper measures being immediately taken, no man ought to be suffered to profess surgery who is not competent to the treatment of wounded arteries, whether injured by accident or in a surgical operation. Loss of limb, or life itself, is the too frequent consequence of such ignorance. Thus, Langenbeck recites the case of a turf-cutter, who let the instrument with which he worked fall against the lower part of his leg, whereby the posterior tibial artery was wounded. The blood gushed out profusely, and the surgeon who was sent for applied a tourniquet to the popliteal artery, and thus stopped the bleeding for a time; but, unfortunately, the tourniquet was kept so long on the limb, that the foot mortified, and sloughed away. (*Bibl. für die Chir.* b. i. p. 231, 232. Gott. 1806.) From the explanations, delivered in the article **HÆMORRHAGE**, it will be seen that, in all bleedings from considerable arteries, nothing is equal to the ligature, as a means of preventing the further loss of blood; and it may be laid down as a standing rule, that each extremity of the wounded vessel should be tied as near as possible to the wound in its coats. As Mr. Hodgson has remarked, "the necessity of tying both ends of a wounded artery is evident from the fact, that the anastomoses in all parts of the body are so extensive as to furnish a supply of blood, which may pass through the lower extremity of the wounded vessel in a sufficient stream to produce an alarming, and, in some instances, a fatal hæmorrhage." (*On Diseases of Arteries, &c.* p. 469.) This correct observation is followed by a case in which the bleeding from the lower end of a divided brachial artery caused the patient's death. Of course, the inference is that both extremities of the vessel ought to have been tied directly after the receipt of the wound. With regard to tying the trunk of an artery in a part of the limb where it can be exposed with facility, when it is difficult to secure its bleeding extremities, as Mr. Hodgson remarks, the practice "was falsely deduced from a knowledge of the fact that the ligature of an artery at a distance from the disease will effect the cure of an aneurism. But, a more intimate acquaintance with the condition of a limb after such an operation, and the processes by which the cure of an aneurism is effected after the modern operation, afford a complete illustration of the inefficacy and danger of this mode of treating a wounded artery; for it is now fully proved, that when an artery is tied a stream of blood continues to pass through it below

the ligature." This well-informed surgeon is aware however, that instances do occur, in which only the upper end of a wounded artery is tied, and yet the patient recovers without hæmorrhage from the lower orifice, which is closed by the natural processes.

In the year 1814, in Holland, I took up the femoral artery, in the middle of the thigh, in a case where the popliteal artery had given way, ten days after the passage of a musket-ball through the ham. I employed only one smallish ligature, which was applied with the precaution of not detaching the artery from its natural connections. The hæmorrhage was effectually stopped, and the wound healed in the most favourable manner. Here, no doubt, the inflammation in the ham had obliterated the portion of the artery immediately below the point at which it had sloughed, or ulcerated; and there might even have been, from the same cause, some deposition of lymph within the upper portion of the popliteal artery, contributing to the success of the operation. But, no doubt, it was the diminution of the impulse of the circulation by the ligature of the femoral artery, which enabled nature to complete the obliteration of the wounded part of the vessel. In 1834, I cut down to and tied the popliteal artery in the University College Hospital, to stop hæmorrhage from the posterior tibial artery, which had been wounded in a boy who, in cleaning a window, slipped, and thrust his leg through a pane of glass. As, in consequence of the house-surgeon having made several ineffectual attempts to stop the bleeding by ligature of the posterior tibial, there was an extensive ill-conditioned wound, I judged it better to tie the popliteal artery than to increase the disturbed state of the parts lower down. The operation, which was attended with no difficulty, succeeded completely, as the ligature of the femoral artery has done in the hands of Dupuytren, Delpech, and others, for the stoppage of hæmorrhage from the tibial arteries in compound fractures of the leg. Sometimes, says Mr. Hodgson, when hæmorrhage takes place, a few days after the bleeding from a wounded artery has been stopped by compression, one extremity of the vessel will be pervious, whilst the other will have closed by the natural processes. Cases have even occurred, in which the upper end of the artery has been closed by the natural processes, whilst those processes failed in effecting the obliteration of the lower extremity of the vessel, from which a serious hæmorrhage took place. (*Hodgson, op. cit.* 475; and *Guthrie, in New Med. and Phys. Journ.* vol. iv. p. 177.) Indeed, in the example in which I took up the femoral artery myself, it was impossible to say positively, whether the blood came from the part of the popliteal artery above, or below the slough in it, as no incision was made into the ham.

It is observed by Mr. Guthrie, that the lower end of a divided artery is more prone to secondary hæmorrhage than the upper; and that when bleeding returns, after having been arrested for a period of four hours, it takes place, in all probability, from the lower end. "This (says he) may always be known by the darker colour of the blood, and by its flowing out in a continuous stream, in the same manner as water rises from a spring, and not with any arterial impulse." (See *Guthrie, On Dis. and Inj. of Arteries*, p. 248.) His observations lead him to conclude, that the retraction and contraction of the lower end of a divided artery, is neither so

perfect nor so permanent, as at the upper end ; and that the internal coagulum (see HÆMORRHAGE) is in many instances altogether wanting, or very defective in its formation (p. 251).

In this work Mr. Guthrie censures the common fear about cutting muscular fibres, in operations to secure wounded arteries ; and, in support of his own view, points out the inconveniences attending the plan of taking up the posterior tibial artery, as described by Mr. Harrison (see *Surgical Anat. of the Arteries*, p. 177, vol. ii. ed. 2). Instead of this, he is an advocate for dividing muscles entirely, or the fibres of a muscle, by an extensive transverse incision, if likely to facilitate the application of the ligature to a wounded artery (p. 261). This last maxim, however, is not entirely new, Desault having long ago recommended cutting the sartorius across to get at the femoral artery ; Scarpa, the pectoralis major, to get at the wounded axillary artery ; and Dupuytren, the anterior scalenus, to reach a particular point of the subclavian. Mr. Guthrie disapproves of the directions given in some of the latest works for the ligature of the wounded posterior tibial and axillary arteries, and makes some remarks on "the manner of securing the ulnar artery, when wounded a little below its origin, and whilst covered by the pronator teres, and the superficial flexors of the forearm ; viz. the flexor carpi radialis, palmaris longus, and flexor digitorum sublimis. Here, instead of regarding the operation as impracticable on account of the intervention of these muscles, or tying the brachial artery, he is an advocate for making a clean incision down to the artery, through all the muscular fibres interposed between it and the surface, avoiding the median nerve, which runs between the two origins of the pronator teres, and placing a ligature above and below the wound in the artery" (p. 271). "It is necessary to be attentive to the course of the great vessels and nerves, but not to the safety of muscular fibres, the division of which leads to no permanent injury" (p. 319). Mr. Guthrie also strongly protests against Dupuytren's practice of tying an artery injured by gun-shot, or a fractured bone above the place of injury, instead of exposing the vessel at the wounded point, and applying a ligature above and below the opening in it ; a subject which I shall notice in subsequent articles. (See FRACTURE and GUN-SHOT WOUNDS.)

The principle, respecting the application of a ligature to each end of every large divided artery, is to be extended also to punctured arteries, one ligature being placed above, and the other below the opening in the vessel.

When an artery is merely cut or torn, but not completely divided, it seems to Mr. Guthrie to be in the same state, with regard to hæmorrhage, as if it had given way by ulceration. It can neither retract nor contract ; and unless pressure be accurately applied and maintained, will continue to bleed until the patient is destroyed. "The practice to be pursued (says he), is to divide the vessel, if it be a small one, such as the temporal artery, when it will be enabled to retract and contract, and the bleeding will soon cease. If an artery of larger dimensions be wounded, a ligature should be applied above and below the wound ; and the vessel may, or may not, be divided between them, at the pleasure of the surgeon. (*On Dis. and Inj. of Arteries*, p. 253.)

From some observations in the article ANEURISM, it will be seen, that when the impulse of the circulation has been lessened by the ligature of the main trunk of an artery, some distance above the wound, the hæmorrhage from the more remote portion of the vessel may sometimes be effectually restrained by pressure, which, previously to the stoppage of one great current of blood to the part, had proved unavailing. This fact is worth remembering in cases in which the arteries of the hand or foot are wounded.

Mortification is observed to be more frequent after the ligature of an artery for a wound than for an aneurism. In wounds Mr. Hodgson, very correctly, I think, refers the difference to the frequent injury of the surrounding parts, and particularly of the veins and nerves, and to the loss of blood, and want of quietude, and proper care, after the accident. The principal anastomosing vessels are also sometimes divided (p. 479).

In the article ANEURISM, I noticed the questions about the propriety and safety of tying both carotids, and whether this could be done without extraordinary risk, when no interval was left between the two operations. With respect to these points, I find that M. Manec is decidedly of opinion, that both the common carotid arteries may be tied at once in the same individual, without any marked or lasting derangement in the functions of different parts of the head. He believes that the numerous anastomoses which exist in the interior of the skull, between the terminating branches of the vertebral arteries and those of the internal carotid, are more than sufficient for the ready conveyance of blood from the former into the latter, and for the prevention of the brain from being sensibly affected by the obliteration of the two common carotids. Externally, the numerous communications between the branches of the external carotids, and those of the two subclavian arteries, more particularly the free anastomosis of the lower thyroid with the superior thyroid arteries, and those of the ascending cervical with the occipital arteries, leave no doubt in M. Manec's mind respecting the correctness of the opinion which he has advanced. He has frequently tied both the common carotids in animals, without the slightest impairment of their intelligence, or of their general health. At the period when he was recording his views of this subject, there was in the dissecting-room of the hospital a large strong healthy dog, on which he had performed this operation four years previously ; and whose intelligence continued perfectly undiminished. So fully convinced is M. Manec of the safety with which it may also be practised on the human subject, that he wished to undertake it on a young man who had an extensive tumor of erectile tissue on the face, but who would not submit to the proposal. (See *Manec, Traité, &c. de la Lig. des Artères*, pl. iv.)

Having explained in the article ANEURISM the plans adopted by some of the most celebrated operators, in cutting down to and tying many of the principal arteries, I will now introduce some additional instruction on this very important subject.

Perhaps, in no operation of tying an artery, is the exclusion of the vein and nerves of so much consequence as it is in that of applying a *ligature to the common carotid artery*. As Dupuytren remarks, this fact depends upon the importance of the organs to which the adjacent nerves are dis-

tributed, viz. the heart, lungs, and stomach. (See *Leçons Orales*, &c. t. iv. p. 17.)

The right common carotid trunk is much shorter than the left; the former arising from the brachiocephalic trunk, the latter from the arch of the aorta. Both terminate opposite the space between the os-hyoides and upper edge of the thyroid cartilage; and behind each of them are the longus colli and rectus capitis anticus muscles, placed in front of the cervical vertebræ. In the lower part of the neck, the trachea is near their inner side; higher up, the thyroid gland; and still higher up, the larynx and pharynx. The external side of the common carotid is in contact with the internal jugular vein, which partly overlaps it; while, between the two vessels, but rather behind them, and enclosed in the same common sheath with them, the pneumogastric nerve descends. In the lower part of the neck, the carotid sheath has behind it the recurrent laryngeal nerve and the inferior thyroid artery. The descending branch of the ninth nerve commonly lies upon the fore part of the sheath, closely connected to it, and about the middle of the neck, forms a plexus, with some filaments from the second and third cervical nerves. At the upper part of the neck this nerve lies rather towards the outer side of the sheath; at the lower, on the inner side. Mr. Harrison has often found it within the sheath, behind the jugular vein. The sympathetic and cardiac nerves are situated between the sheath and the rectus anticus major muscle. The common carotid artery is covered below by the skin, platysma, and cervical fascia, and also by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles. Opposite the upper rings of the trachea, it is crossed by the omohyoideus. But, from this point to its bifurcation, the vessel is covered only by the skin, platysma, and fascia. The omohyoideus, as it proceeds from the shoulder behind the sterno-mastoid muscle, divides the artery into an upper and lower portion, and the side of the neck into two triangular spaces. In the lower triangle, bounded by the trachea, clavicle, and omohyoideus itself, the common carotid is concealed by the sternal origin of the mastoid muscle, and lies deeply under the sterno-hyoid and sterno-thyroid muscles. But, in the upper triangle, bounded externally by the margin of the sterno-mastoid muscle, above by a transverse line denoting the uppermost extent of this space below the os-hyoides, and on the inside by the omohyoideus, the vessel is much more superficial. Here, however, a plexus of veins often lies directly in front of the carotid sheath. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 234; *Quain's Anatomy*, ed. 2, p. 437; *Harrison's Anat. of Arteries*, vol. i. p. 19, ed. 2; *Manec, Traité de la Lig. des Artères*, No. i. pl. iv.) A chain of absorbent glands lies near the carotid sheath, principally on its external side, and is partly concealed by the sterno-mastoid muscle, and covered by the cervical fascia. In young subjects these glands are large and numerous; "they are frequently enlarged and indurated by chronic inflammation; the muscles and fascia press them closely to the vessels; they become fixed, and have a pulsation communicated to them, so as to resemble aneurism." (*Harrison*, op. et. vol. cit. p. 21.)

The operation of tying the common carotid is sometimes performed while the patient is in the sitting posture; but, on account of the chance of his

becoming faint, I consider the recumbent position best, with the chest somewhat raised, the neck moderately extended, and the chin turned towards the opposite side. If the artery is to be tied below the omohyoideus, the front edge of the sterno-mastoid muscle is to be first felt for, and an incision, three inches long, made in the direction of it, commencing opposite the cricoid cartilage, and directed towards the sterno-clavicular articulation, a little above which it is to terminate. The second stroke of the knife divides the platysma myoides and cervical fascia, so as to bring into view the fibres of the sterno-mastoid muscle. Unless this last incision be made over the latter muscle, it is best to pinch up a portion of the cervical fascia with the forceps, and cut it across, so as to make a small opening in it for the introduction of a director, on which it is to be slit up. (See *Quain's Anatomy*, p. 450, ed. 2.) An assistant now draws the inner margin of the wound, and the sterno-thyroid and sterno-hyoid muscles, towards the median line, while the surgeon himself draws the external margin of the wound, and the sterno-mastoid muscle, outward. For this purpose, blunt hooks are sometimes preferred, as not concealing the parts so much as the fingers.

The *omohyoideus* is now seen running across the wound in the form of a red cord, and above and below it are the vein and artery, enclosed in their common sheath.

This sheath should be opened over the artery, and not over the vein, with the aid of a pair of forceps and a director. If the jugular vein swell up so much as to conceal the parts, pressure is to be made on it at the upper angle of the wound. (See *Velpeau, Nouv. Elém. &c.* t. i. p. 241.) Then an eye-probe, or aneurism-needle, is to be conveyed between the vein and artery, and directed inwards under the posterior surface of the latter, without meddling with the pneumogastric nerve, the great sympathetic, or any of their branches.

It seems to M. Velpeau, that if the surgeon were to cut at first to the inner side of the mastoid muscle, there would be some risk of mistaking the sterno-hyoideus for it, and getting wrong. He thinks it better, therefore, to cut down upon the surface of the sterno-mastoid muscle, a few lines from its anterior margin. As the coats of the vein are very thin and easily torn, the knife is never to be applied near it.

If the sheath were not duly opened, the pneumogastric nerve, situated within its posterior layers, between the carotid and jugular vein, might possibly be tied, and the cardiac nerves and descendens noni be in danger of suffering the same fate.

The ligature of the common carotid above the omohyoideus is rendered easier by the more superficial situation of the vessel, which is merely covered by the skin, platysma, and the cervical fascia. The incision is to commence a little below the level of the angle of the jaw, and be continued down to the extent of about three inches in the interspace between the sterno-mastoid muscle and the larynx, in the upper triangle of the neck. The skin and platysma having been divided, the cervical fascia is to be pinched up with a pair of forceps, and an opening made in it. Then a director is to be introduced, and the operation finished according to the directions already given, as applicable to that below the omohyoideus.

In the operation of applying a *ligature to the*

subclavian artery, on the outside of the scalenus anticus, the patient is to lie on his back, with his shoulders somewhat raised. The head and neck are to be turned towards the sound side, while an assistant depresses the shoulder, and raises the arm from the side. The first incision is to be made transversely, an inch above the clavicle, as Velpeau directs, or near, or even upon it, as many other surgeons prefer, from the outer edge of the sternomastoid muscle to the front edge of the trapezius. After the integuments have been cut, the platysma myoides is to be divided. The external jugular vein itself may generally be drawn aside with a blunt hook; but, if this cannot be readily done, a double ligature must be put under the vein and tied, after which it is to be cut through in the interspace. Then the cervical fascia is soon exposed, which is to be cautiously opened, by pinching a piece of it up with the forceps, and making a small opening, which is to be enlarged with the aid of a director. The edge of the scalenus anticus can then be immediately felt under and within the sternomastoid muscle. After having lacerated or separated the cellular tissue, absorbent glands, &c., in the bottom of the wound with a probe, or a director, the finger is conveyed towards the insertion of the scalenus anticus, where the tubercle of the first rib will be felt, a little behind and on the outside of which the artery is situated.

When once the artery is found, it is not necessary to bring it into view; for the nail being applied to its posterior and external side, serves as a guide for the bent eye-probe or aneurism-needle, the point of which is to be passed from before, backwards, and a little from without inwards, the surgeon keeping his finger over the artery, between it and the lowermost nerve of the brachial plexus, so as to steady the vessel. (See *Velpeau, Nouv. Elém. &c. t. i. p. 229.*)

With reference to the *ligature of the external iliac artery*, I have but little to add to the account given of this subject in the article ANEURISM. From the sacro-iliac symphysis, where the common iliac artery bifurcates, down to the crural arch, the external iliac artery describes a gentle curve, which is more marked in the female than the male subject, and the convexity of which is turned outwards and backwards. The artery descends along the inner margin of the psoas muscle, to which it is connected by a thin membrane, derived from the iliac fascia, situated behind the artery. Although the production from the iliac fascia is so thin that the artery and vein can be seen through it, yet it is sufficiently strong to prevent them from being displaced or separated. (See *Harrison's Surgical Anat. of the Arteries*, vol. ii. p. 117.) The vein lies to the inner side of the artery, and at first rather behind it; but, near Poupart's ligament, it is on the same plane as the artery, resting upon the os pubis, and upon a few fibres of the psoas and pectineus muscles. The anterior crural nerve is on the iliac side of the artery, but on a plane posterior to it, and separated from it by the psoas between which and the iliacus internus the nerve covered by the iliac fascia is imbedded. "Two or three small branches from this nerve, and from the lumbar plexus, are connected to the artery, and descend along its external side. These branches are distributed to the spermatic cord and to the integuments of the groin. (See *Harrison, op. cit.*) The ureter, in its descent behind the peritoneum,

crosses over the anterior surface of the external iliac artery at its commencement, and so does the vas deferens near its termination. As for the peritoneum, it is connected to the external iliac artery merely by loose cellular tissue, and below quits the vessel entirely to be reflected over the posterior surface of the parietes of the abdomen. The only branches of importance, which the external iliac artery gives off, are the circumflexa ilii and the epigastric, which usually arise opposite the ilio-pectineal line, though sometimes a quarter or half an inch above, or below this point. The absorbent glands, which lie in the course of the external iliac artery, being sometimes enlarged, excite a suspicion of diseases which do not exist. On the right side, the cœcum, and, on the left, the sigmoid flexure of the colon, are the only viscera, interposed between the external iliac artery and the parietes of the abdomen. As MM. Bogros and Velpeau have noticed, nothing is easier, in a thin person, whose abdominal muscles are relaxed, than to make effectual pressure on this artery. M. Velpeau had an opportunity of ascertaining the truth of this observation in a young man, who met with an accidental wound of the artery above the origin of the epigastric, requiring the injured vessel to be tied without delay. (See *Velpeau, Nouv. Elém. de Méd. Opér. t. i. p. 172.*)

In Abernethy's method of tying the external iliac artery, an incision is made, about three inches and a half in length, in the direction of the artery, down to Poupart's ligament. The aponeurosis of the external oblique muscle being thus exposed, is to have an opening cautiously made in it; and a director being now introduced, the aperture is enlarged in the direction of, and to the same extent as, the wound in the integuments. "The internal oblique and transverse muscles, which are closely connected with each other, are to be carefully cut into at the lower part, so as to allow a director, or the point of a finger, to be introduced below them, when they also are to be divided, the finger separating them from the fascia transversalis and peritoneum. The fascia transversalis, running from Poupart's ligament to the peritoneum, is now to be torn through with the nail, immediately over the pulsating artery, and the peritoneum is to be separated by the finger, and pushed upwards until sufficient room is obtained; which, in this, as well as in all other operations on the iliac arteries, is sometimes difficult, on account of the protrusion of the intestines, covered by the peritoneum, when the patient is not sufficiently tranquil. The artery is yet at some depth, and covered by a dense cellular membrane, connecting it to the vein on its inside, and which must be torn through with the nail. The aneurism-needle should be passed between the vein and the artery, and the point made to appear on the outside of the artery." (See *Guthrie, On Dis. &c. of Arteries*, p. 373.) This description, with the observations in the article ANEURISM, will suffice to render Abernethy's plan very intelligible.

To the account of Sir Astley Cooper's method of taking up the external iliac artery, given in that part of the Dictionary, I have nothing to add.

In the article ANEURISM, a description is given of the operation of *tying the femoral artery* in the upper third of its course. If it were indispensable to apply a ligature to it in the groin, or just below the crural arch, the surgeon should remember, that

here the situation of the artery corresponds to the mid point between the anterior superior spinous process of the ilium and the tuberosity of the os pubis; though, in women, in whom the pelvis is wider, the artery is rather nearer the pubes. The vessel may also be readily felt as it is passing over the os pubis, being only covered by the integuments, superficial fascia, some lymphatic glands, and the fascia lata. Immediately below Poupart's ligament, the femoral vein lies on the pubic side of the artery. The anterior crural nerve lies about half an inch away from the iliac side of the artery, imbedded between the iliac and psoas muscles. (See *Harrison's Surg. Anat. of Art.* vol. ii. p. 136.) In the operation, the limb should be extended and rotated outwards; an incision made, beginning about an inch above Poupart's ligament, and extended downwards in the direction of the artery, to the distance of two inches below this ligament. The layers of the superficial fascia are then to be divided to the same extent; and any lymphatic gland in the way pushed to one side, or, if enlarged and diseased, removed. The fascia lata is next to be divided, and the sheath of the femoral vessels pinched up with a pair of forceps, and cautiously opened. Lastly, the aneurism-needle, or eye-probe, used for the conveyance of the ligature under the artery, is to be introduced on the pubic side of this vessel, between it and the vein, so as to leave the latter completely safe. As in some individuals the origin of the profunda is unusually high up, and of nearly the same size as the femoral, one of them might be mistaken for the other. The profunda, however, is the more external of the two. The effect of pressure on each, in checking the hæmorrhage, or the pulsation of an aneurism, will also be a guide to the operator. (See *Harrison*, op. et. vol. cit. p. 160.) Sometimes a double femoral artery has been met with.

The direction, given by M. Malgaigne, to place the ligature as closely as possible above the origin of the profunda (*Man. de Méd. Opér.* p. 188), if adopted, would be very likely to be followed by secondary hæmorrhage, for reasons elsewhere explained. (See *HÆMORRHAGE*.)

The operation of *tying the femoral artery in the middle third of the thigh*, not having been fully described in the article *ANEURISM*, I annex the following particulars:—This artery, in its course from the crural arch to the lower third of the thigh, runs in the direction of a line, which, drawn from the centre of Poupart's ligament, descends obliquely inwards round the limb to the middle of the popliteal space. This description is nearly correct; but, as Dr. Quain observes, as this line runs along the inner surface of the thigh, its course is more oblique than that of the vessel, which is placed much nearer the shaft of the femur. (*Elem. of Anat.* p. 505, ed. 2.) In the middle third of the thigh, the femoral artery is more deeply placed than in the upper, because, in addition to the integuments, superficial fascia, and fascia lata, it has the sartorius lying upon it, beneath which there is also another fascia extended over it, from the adductor muscle to the vastus internus. This fascia, though thin above, becomes very dense where the artery approaches the opening in the adductor magnus. In the groin, the femoral vein lies close to the inner side of the artery, but, as it descends, it gets more under the latter vessel, and, in the popliteal space, it is situated quite to the outer side of it.

An incision, three inches in length, is to be made along the inner edge of the sartorius, which is the common rule, and perhaps better than Lisfranc's modification, which consists in making an incision of this length in the mid space between the gracilis and sartorius; for, by exposing the fibres of the latter muscle, their very course affords useful instruction to the surgeon; for he then knows immediately where he is, and what ought to be done. The integuments and superficial fascia having been divided, and the fascia lata to the same extent, the inner edge of the sartorius is exposed. This is to be gently raised, and drawn outwards. The fascia, extending from the vastus internus to the adductor, and covering the artery, is brought into view, and with the aid of a pair of forceps, and a director, it is to be cautiously opened, by which means the sheath of the femoral vessels will be exposed. Here the long saphenous nerve lies within the sheath, on the anterior and external side of the artery, and care should be taken not to include it in the ligature. Lastly, the aneurism-needle is to be conveyed under the artery, between it and the vein. In making the incision through the integuments, the great saphenous vein should be avoided, by not directing the knife too obliquely downwards and backwards.

In addition to what has been stated in the article *ANEURISM*, respecting the *ligature of the brachial artery*, I may observe, that the course of this vessel corresponds to an oblique line drawn from the armpit to the middle of the bend of the elbow. The median nerve, which above runs along its radial margin, soon gets in front of it, and, crossing it very obliquely, passes quite to its ulnar side below. Two satellite veins usually accompany the artery, and even sometimes cover it, and thus separate it from the median nerve. The ulnar and internal cutaneous nerves, which lie near it above, separate further and further from it as they descend, in order to reach the inner part of the fore-arm. The artery, lying at first near the humerus, between the coraco-brachialis and the tendon of the latissimus dorsi, afterwards passes over the insertion of the coraco-brachialis, and gets upon the brachialis anticus, a little behind the inner margin of the biceps, which last muscle it accompanies to its termination. In the supine state of the hand, the brachial artery is less covered by the biceps; and hence, in the operation of taking it up, this position is advantageous. (See *Manec*, *Man. de Méd. Opér.* p. 166.) In thin subjects, the fascia is almost contiguous to it, and sends off a duplicature to include the artery, its two accompanying veins, and the median nerve, all which form, as it were, one common fasciculus.

The whole is covered by the common integuments, and in the lower third of the arm, by the trunk of the basilic vein. The anomalies of the brachial artery are very frequent. Velpeau, and most other surgeons, have seen it divide near the axilla, and at nearly every other point between this and the elbow. In one subject, Velpeau found its bifurcation take place two inches above the trochlea of the humerus, to form the ulnar and posterior interosseous. In another, the latter was completely independent of both the ulnar and the radial. Sometimes the two trunks, produced by the bifurcation, pass down to the fore-arm parallel to one another; in other instances, they cross once, or several times; and it is not uncommon to

find one piercing the fascia, so as to get immediately under the skin, while the other, which then gives off the radial and the interosseous, retains its ordinary relations. (See *Velpeau, Nouv. Elém. de Méd. Opér.* t. i. p. 210.)

In the operation of *placing a ligature on the brachial artery at the bend of the elbow*, the surgeon should remember, that the course of the vessel here corresponds to a line drawn obliquely inwards and upwards, from the middle of the front of the elbow, to the inner border of the biceps. Its course is also denoted by the median basilic vein, which passes under the skin, almost in the same line as the artery. An incision, between two and three inches in length, is to be made through the skin, on the inner side of this vein, which is to be carefully drawn out of the way. Then, with the aid of a director, the fascia, and the fibrous production given off from the tendon of the biceps, are to be divided; which having been accomplished, the artery will present itself, bounded on the right and left by its two venæ comites, the median nerve lying three or four lines from its inner, and the tendon of the biceps the same distance from its outer, border. To facilitate the passage of the aneurism-needle or director under the artery, the elbow is to be a little bent, and the instrument passed from within outwards under the vessel. (See *Manec, op. cit.* p. 166.) If the operation were performed somewhat higher, the surgeon must remember, that two or three inches above the trochlea of the humerus, the median nerve would begin to be in front of the artery.

In the *upper part of the arm*, the brachial artery lies at the inner border of the coraco-brachialis, and has the median nerve at first external to it, and then in front of it. Below the insertion of the coraco-brachialis, it is situated at the inner edge of the biceps. Four circumstances are enumerated as guides for the external incision:—1. The inner edge of the coraco-brachialis above, and that of the biceps below. 2. A line drawn from the middle of the axilla to the middle of the bend of the elbow. 3. Placing the fingers on the median nerve, and cutting on its inner side. (*Lisfranc.*) 4. The pulsations of the artery.

The knife is carried in the direction of the artery from above downwards in the right arm, and from below upwards in the left, and an incision made in the integuments, about three inches long. With the forefinger, the surgeon next endeavours to feel the median nerve, which presents itself as a round very hard cord; and to distinguish the artery by its pulsations. He then divides, with the aid of a director, one after the other, the fascia, and the sheath given off by it to the median nerve; and breaking, with the end of a probe or director, the fibro-cellular covering of the vessels, separates the artery from the veins, and puts a ligature under it. Except when anomalies occur, the operation is simple. M. Velpeau has only once seen the median nerve under the artery. In all ordinary cases, it is the first cord met with behind the inner margin of the biceps. (See *Velpeau, Nouv. Elém. &c.* t. i. p. 211.)

As some very celebrated surgeons have made the serious mistake of tying the median nerve for the brachial artery, I advise the practitioner never to tighten the ligature, until he has tried the effect of pressure on what he supposes to be the artery.

In order not to mistake the ulnar for the me-

dian nerve, and to be led to seek for the artery where it will not be found, it is an excellent rule to proceed in the operation from the anterior to the posterior part of the arm. (See *Manec, Man. de Méd. Opér.* p. 167.)

Ligature of the Radial Artery behind the Carpus.—If the thumb be forcibly extended, the tendons of its great abductor and long extensor will be made very prominent behind. In the depression between them, the pulsations of the radial artery can be felt. The thumb being drawn away from the forefinger, an incision, an inch and a half in length, is to be made in the direction of the foregoing tendons, first through the skin, and then through the fascia. The artery is then to be separated from some veins and nervous filaments, with a probe or director. (See *Manec, op. cit.* p. 163.)

Ligature of the Radial Artery in the Lower Third of the Fore-arm.—Here the artery can readily be felt, being only covered by the fascia and the skin. On each side of it is a vein; but the radial nerve is considerably to the outer side of it, having passed under the supinator radii longus, a little below the middle of the fore-arm. An incision, two inches and a half long, is to be made a little way from the radial margin of the flexor carpi radialis, between this and the supinator longus. The fascia is to be opened, and the ligature passed from within outwards, or from without inwards, as the surgeon may choose, as it is a matter of indifference, the nerve being out of danger.

Ligature of the Radial Artery in the Upper Third of the Fore-arm.—Here the artery runs in the space which separates the supinator radii longus from the pronator teres and palmaris longus, covered by the internal border of the first of these muscles, and of course by the fascia and the skin. It is always accompanied by two veins, and has the radial nerve at its outer side. Its course is accurately indicated by a line, drawn from the middle of the bend of the elbow to the mid point between the styloid process of the radius and the tendon of the palmaris longus.

In the direction of this line, M. Roux makes an incision, about two inches and a half in length, commencing a little below the elbow. If the median vein is met with, it is pushed aside. The fascia is then slit up with a director, and the border of the long supinator drawn outwards, without dividing it. The artery having been brought into view, the aneurism-needle, or eye-probe, is passed under it from without inwards, on account of the nerve. (See *Manec, Man. de Méd. Opér.* p. 164.)

Others adopt the following plan:—A finger is to be put on the insertion of the tendon of the biceps. A little below this insertion, an incision, about two inches and a half in length, is to be made in the integuments, in the oblique direction, denoted by the inner edge of the supinator radii longus. The subjacent fascia is then to be divided, and the inner edge of the supinator muscle drawn a little to the outer side of the arm: in the space between that muscle and the flexor carpi radialis, the radial artery immediately presents itself, passing over the tendon of the pronator radii teres. Below this it lies upon a few fibres of the flexor sublimis and the flexor longus pollicis. Afterwards it runs down between the latter-named tendon and the flexor carpi radialis. (See *Camper's Demons. Anat. Pathol.* lib. i. tab. 1, fig 2.)

Ligature of the Ulnar Artery at the Wrist.—Here the artery passes on the radial side of the pisiform bone, with the ulnar nerve on its inner or ulnar side, and a vein on each side of it. In this place an incision, two inches long, is to be made through the skin, cellular tissue, and palmar fascia, one after the other. The artery having been thus exposed, an eye-probe is to be passed under it from without inwards.

Below the middle of the fore-arm, the ulnar artery is superficial, and may easily be taken up by making an incision upon the radial side of the flexor carpi ulnaris, between the tendon of which muscle and that of the flexor sublimis digitorum, the vessel is situated. The artery, however, will not be reached until a thin aponeurosis under the fascia of the fore-arm has been divided. The nerve is rather more under the tendon of the flexor carpi ulnaris than the artery. When the ulnar artery arises from the brachial above the elbow, it sometimes pierces and runs above the fascia, and is easily taken up in any part of its course.

For bringing into view *the ulnar artery at the upper third of the fore-arm*, the situation and breadth of the flexor carpi ulnaris muscle must first be ascertained. An incision is then to be made from above downwards, beginning two inches below the inner condyle of the humerus, and following the course of the inner margin of the above muscle to the extent of two inches and a half. The fascia is then to be divided; and the flexor carpi ulnaris drawn a little away from the flexor sublimis. In this opening, rather under the margin of the latter muscle, the ulnar artery will be felt with the finger, continuing its course over the flexor profundus. The ulnar nerve is situated on the ulnar side of the artery. Mr. Guthrie's opinions, respecting the propriety of dividing the muscles which conceal the upper third of the ulnar artery, have been noticed in the beginning of the present article.

Ligature of the Anterior Tibial Artery on the Foot.—The anterior tibial artery becomes superficial about six inches above the ankle, from which point it descends between the tendon of the tibialis anticus and that of the extensor of the toes. It passes with these tendons under the annular ligament, and rather nearer to the internal malleolus than the external; thence inclining inwards, it penetrates between the first and second metatarsal bones to the sole of the foot, where it inosculates with the external plantar artery. The dorsal nerve of the foot is at its inner side; its corresponding veins lie on either side. It is covered—1st, By a thin fibro-cellular expansion, separating it from the adjoining tendons. 2ndly, By adipose cellular tissue. 3rdly, By the fascia of the instep. 4thly, By the common integuments. On the instep, the first tendon of the extensor communis digitorum pedis, lies upon the outer side of the artery; that of the extensor of the great toe upon its inner side.

An incision, two inches and a half long, is made in the skin, in the direction of an oblique line from the middle of the instep to the first interosseous space. The skin, adipose substance, and fascia, are to be divided; the fibro-cellular aponeurosis, between the tendons of the first two toes, opened; and the artery tied, after being separated, by means of a director, from the accompanying nerve and veins. (*Velpeau*.)

Ligature of the Anterior Tibial Artery in the Leg.—The two upper thirds of this artery lie close to the interosseous ligament; but lower down the artery advances towards the outer side of the spine of the tibia; consequently, the higher it is, the more deeply it is situated. The two veins accompanying it inosculate across it by several small branches. The anterior tibial nerve crosses over it obliquely inwards and downwards, though sometimes it continues on its outer side down to the instep. The artery, veins, and nerve, are included in cellular tissue, which does not, however, form a true sheath for them. Above, the artery lies between the tibialis anticus and the extensor communis; in the middle of the leg, between the tibialis anticus and the extensor of the great toe; and still lower down, between the extensor of the great toe and the extensor communis.

Ligature of the Anterior Tibial Artery in its Lower Third.—The skin, the subcutaneous fat, the cellular tissue, and the fascia, are to be divided in succession, to the extent of about three inches, and in the direction of a line drawn from the mid point between the head of the fibula and spine of the tibia to the instep. Then, with a director or the fore-finger, the tendon of the extensor muscle of the great toe is to be separated from that of the tibialis anticus, pushing it outwards towards the extensor communis, if the operation be at the upper part of the lower third of the leg; but inwards, if the operation be done quite at the inferior extremity of the leg. Nothing, then, remains to be done, but to separate the artery from its accompanying veins, and from the anterior tibial nerve, which in this part of the limb is at its inner side, having crossed it from the outer in its descent. (See *Manec*, pl. xii. fig. 1; *Velpeau*, *Nouv. Elém.* &c. t. i.)

Ligature of the Anterior Tibial Artery in its Middle or Two Upper Thirds.—Lisfranc makes an incision extending obliquely from below upwards, from the spine of the tibia towards the fibula. Having cut transversely through the fascia, the interspace between the tibialis anticus and the extensors is sought for.

In the ordinary method an incision is made in the track of the artery, as determined by the line above specified, about an inch on the outside of the spine of the tibia. The skin and fascia are divided to the extent of three inches. The muscular interspace, at the bottom of which the artery will be found close to the interosseous ligament, is denoted by a yellowish line, and is more distinct at the lower part of the wound. In order to convey the ligature round the artery, Velpeau passes a director under it very obliquely, from below upwards, and from the fibula towards the tibia.

Ligature of the Posterior Tibial Artery.—From its origin, a little below the popliteus muscle, to its division into the external and internal plantar arteries, the posterior tibial artery follows very precisely the direction of a line, with a slight convexity inwards, from the middle of the upper part of the calf to a point half an inch behind the internal malleolus. Two veins usually accompany it, sometimes forming by their anastomoses a complete network round it. In the upper part of the leg, for the first two inches, the posterior tibial nerve lies to the inner or tibial side of the artery, and then passes over it to the outer

or fibular side. In the two upper thirds of the leg, the posterior tibial artery is deep seated, lying in the upper third upon the tibialis posticus, in the middle third upon the flexor digitorum communis; while lower down it is separated from the tibia only by fat and cellular tissue. From the gastrocnemius and soleus, which muscles lie over its two upper thirds, it is separated by the deep crural fascia. In the lower third, no muscles cover it.

In the arch of the os calcis, the posterior tibial artery is in contact with the fibrous sheath of the flexor communis digitorum, about half an inch from the posterior border of the inner malleolus. Here the nerve is behind it, the veins on either side. The artery is enveloped in cellular and adipose tissue. The internal ligament of the tarsus, a fibrous layer continuous with the fascia of the leg, after covering the artery, becomes blended with the dense cellular tissue interposed between the vessel and the skin. (*Velpeau*.) Between the internal malleolus and the lower part of the calf, the posterior tibial artery is somewhat further from the internal edge of the tibia, and the nerve is rather on its outer side than behind it. The deep-seated fascia, which is here very thin, keeps the artery bound down upon the flexor longus communis digitorum. Superficial to this fascia is the tissue that fills the sheath of the tendon of Achilles, and then the common fascia of the leg directly under the skin.

Opposite the calf, the posterior tibial artery is very deeply seated, almost on the same plane as the posterior surface of the tibia, and much nearer to its external or fibular edge than its internal. It is covered by a strong fascia, that lies over the flexor muscles; and then by the tibial portion of the soleus; the internal head of the gastrocnemius; the fascia of the leg; the subcutaneous cellular tissue, in which are found the great saphenous vein and the long saphenous nerve; and lastly the skin. (See *Velpeau*.)

In this operation the leg is to be bent and laid upon its outside.

Behind the malleolus internus.—An incision, slightly curved, with its concavity forwards, is to commence an inch above, and to terminate an inch below the posterior edge of the malleolus internus, and to be at least three lines behind it. It will, therefore, be between the malleolus internus and the tendo Achillis. If the operation is to be performed in the hollow of the os calcis, it is necessary, as *M. Velpeau* directs, to divide the tissues cautiously, layer by layer, and to introduce a director under the fascia, previously to its division, lest the artery, which is sometimes very superficial, be wounded. If the incision were made too near the malleolus, the fibro-synovial sheath of the groove, which that process contributes to form, would be opened: if too far backward, the artery would be more difficult to find. (See *Velpeau, Nouv. Elém. de Méd. Opér. t. i.*) In fact, behind the lower end of the tibia, the tendons of the tibialis posticus and of the flexor communis digitorum pass in a kind of furrow. Along with these two tendons, but somewhat nearer to the os calcis, the posterior tibial artery descends to the sole of the foot.

The depth of the posterior tibial artery in the two upper thirds of the leg, makes it difficult to take it up in these situations. When necessary,

however, it may be exposed, and tied above and below the wound in it, by proceeding as follows:—An incision, four inches in length, is made along the inner side of the tibia; the soleus muscle detached from the bone to the same extent, and reflected. The internal saphenous vein is to be avoided. Under the soleus muscle is found the fascia, which separates the muscles of the calf into superficial and deep-seated. When this fascia has been divided, the posterior tibial artery may be seen, or felt, deeply situated, running on the tibialis posticus and flexor muscle of the toes. (See *Haller, Icon. Anat. fasc. v. tab. 5; Manec, De la Lig. des Artères, fol. Paris, 1822, pl. 13.*)

The method of trying to take up the posterior tibial artery, by making the incision at the inner and posterior edge of the tibia, is disapproved of by *Mr. Guthrie* on account of its difficulties. "The operator (says he) has cut his four inches, has turned up the edge of the gastrocnemius, and has insinuated his director under the head of the soleus, which he has also sliced away from the bone. The artery is still an inch outwards bound down by a strong fascia," which "must be cut immediately over, or by the side of the artery: it will not do to separate it from the bone, and then to push it outwards or towards the fibula; it cannot be done." Then supposing the fascia to be divided in the best way, *Mr. Guthrie* deems the separation of the two veins from the artery, and the passage of the aneurism-needle under the artery from without inwards, so as to avoid the nerve, almost impracticable. "If a bystander should inquire why this most painful, difficult, bloody, tedious, and dangerous operation is done, the answer would be, solely because it was not usual to make a longitudinal incision in the muscles of the calf of the leg,—an incision, which, if made by accident, would be pronounced to be one attended with little danger, and not likely to lead to any subsequent detriment." (See *Guthrie, On Inj. and Dis. of Art. p. 259.*)

Instead of this method, *Mr. Guthrie* advocates the following:—An incision is to be made, six or seven inches in length, through the integuments and muscles of the calf down to the fascia. If the case is a gun-shot wound, the centre of the incision is to be on a line with the shot-holes; or if they are diagonal to each other, between them. The smoothness of the fascia points it out; and the loose cellular membrane, connecting the divided muscles to it, allows the edges of this long incision to be easily separated and the fascia cut, so as to expose the nerve, artery, and veins. The tourniquet is now to be unscrewed, and the bleeding denotes where the artery is injured. The knife may be applied perpendicularly to the fascia, and the artery laid bare for three or four inches in extent (p. 261). Perhaps the length of the incision, as here described, is rather greater than actually necessary. Five inches will afford a great deal of room; but, where the muscles of the calf are very bulky, it will be requisite to make the wound long.

Ligature of the Peroneal Artery.—Here, in following *Mr. Guthrie's* directions, the incision should also be made through the muscles of the calf, towards the fibular side of the leg; and after the deep fascia under them has been divided, the artery will be found covered by the fleshy fibres of the flexor longus pollicis, at any point below three

inches and a half from the head of the fibula. These fibres having been divided, the artery will be found close to the inside of the bone. Above the point specified, the artery lies upon the tibialis posticus, under the deep fascia interposed between it and the muscles of the calf. No large nerve accompanies it.

Ligature of the Axillary Artery.—In proportion as this vessel approaches the hollow of the axilla, it gets nearer to the vein, and becomes surrounded by those nervous fasciculi, by means of which, one portion of the brachial plexus communicates with another. Hence, to cut down to the artery in this place in the living body, and to tie it separately, is acknowledged to be an arduous task. The difficulty is further increased by the distance of the vessel from the surface. Hence, M. Manec objects to any attempt being ever made to apply a ligature to the artery between the pectoralis minor and the lower border of the subscapularis. Independently, says he, of the difficulties of the operation, this part of the axillary artery would be unfavourable to its success, on account of the several branches which are given off from it, near one of which the ligature must be placed.

Directly the axillary artery has arrived opposite the lower border of the great pectoral muscle, the difficulty ceases. Here the brachial plexus no longer exists; each of the different nerves arising from it has taken the course to its particular destination, and the artery is only covered by the integuments and fascia. Behind, it rests upon the tendons of the teres major and latissimus dorsi; in front, it corresponds to the coraco-brachialis, from which it is separated by the median nerve. At its inner side are the internal cutaneous nerve, and the axillary vein, which sometimes consists of two or three branches, and renders the dissection of the artery more tedious. Farther backward than the axillary vein are the ulnar and musculo-spiral nerves. The relation of these last nerves to the artery it is of great importance to recollect, in order that neither of them may be mistaken for the median nerve.

In the operation of taking up the extremity of the axillary artery, the patient should be placed upon his back, and the arm raised from the side. An incision, two inches and a half in length, is to be made six or eight lines behind the anterior margin of the axilla, through the skin and subcutaneous cellular tissue. A piece of the fascia is then to be lifted up with the forceps, and an opening made in it, by cutting transversely, close to the end of the forceps; then a director is to be passed into the opening, and the fascia slit up to the extent of the external wound. If the fascia be tough and dense, so as not to afford convenient room, Manec recommends the incision in it to be converted into a crucial one. These things having been accomplished, the further use of the knife is not necessary. The anterior edge of the wound being now lifted up, the coraco-brachialis will be seen, and the median nerve at its inner side. This nerve being detected, the artery will be found behind it.

M. Manec offers valuable cautions with reference to the manner of avoiding the serious mistake of supposing the ulnar or musculo-spiral nerve to be the median. To escape this blunder, he very properly insists upon the prudence of proceeding backwards from the coraco-brachialis, for in doing

so the first nerve arrived at is the median. (See *Manec, Traité de la Lig. des Artères*, fol. Paris, 1832, Expl. of pl. 6.) In the case of a wound, however, the surgeon has not exactly the choice of the place for the application of the ligature to the axillary artery. Here he must obey the rule of applying it to the wounded part of the artery, and putting one ligature above and another below the bleeding orifice; or if the artery be completely severed, both its extremities will require to be tied.

In taking up the axillary artery, when it is wounded, Scarpa believes that nothing tends more to embarrass the surgeon, than an injudicious smallness of the first incision through the skin and such other parts as conceal the wound in the artery. An assistant must compress the vessel, from above the clavicle, as it passes over the first rib. When the weapon has penetrated from below upward, directly into the axilla, the surgeon is to make a free dilatation of the wound upon a director, or his finger. This must be done to a sufficient height to expose a considerable portion of the artery, and the precise situation of the wound in it.

When the weapon has pierced obliquely, or from above downwards, through a portion of the great pectoral muscle, into the axilla, Scarpa advises the surgeon to cut through the lower edge of this muscle, and enlarge the wound, on a director, or his finger, so as to bring fairly into view the injured part of the artery. The thoracic arteries, divided in this operation, must be immediately tied. The clots of blood are then to be removed, and the bottom of the wound cleaned with a sponge, by which means the opening in the axillary artery will be more clearly seen. As this vessel lies imbedded in the brachial plexus of nerves, the surgeon must take care to raise it from these latter parts with a pair of forceps, before he ties it. Two ligatures will be required; one above, the other below, the wound in the artery.

ARTERIOTOMY (from *ἀρτηρία*, an artery, and *τέμνω*, to cut). The operation of opening an artery, and taking blood away from the system in this manner, for the purpose of preventing, alleviating, or curing disease. The only arteries of any size from which blood is ever taken in practice are the trunk and branches of the temporal artery, which lie in such a situation that after the due quantity of blood has been taken away the bleeding can be readily stopped by compressing the wounded part of the vessel against the neighbouring portion of the cranium. A narrow sharp-pointed bistoury, or a lancet, a basin for the reception of the blood, a compress, and a roller, are the only things required. In general, it is best to open the trunk of the temporal artery; but sometimes its frontal or occipital branch will yield blood enough. When the part of the artery which the surgeon chooses to open lies near the surface and its pulsation is very distinct, and even visible, it may be opened at once with a lancet. But, in many instances, it is better first to make a cut in the skin, and then puncture the vessel. In all cases, the surgeon should recollect, — 1st, That the temporal artery and its branches are covered by the skin, adipose cellular tissue, a thin aponeurosis, and the slender and pale fibres of the anterior auris muscle. 2ndly, That the trunk of the artery divides in the temple, about fifteen lines above the zygoma, and is situated about four lines in front of the meatus

auditorius. 3rdly, That its frontal branch runs forward from its origin, and its occipital branch in the opposite direction. A good place for the puncture is about four lines above the zygoma. In many instances, the requisite quantity of blood cannot be drawn by this operation, as every surgeon of experience must have observed. In order to prevent the blood from trickling down over the bedding or clothes, when it does not issue in a jet, the French make a little gutter with a piece of card for conveying it into the basin. After the proper quantity of blood has been taken away, a graduated compress and a few turns of a roller round the forehead, temple, and occiput, are to be applied. In a few cases, notwithstanding pressure, the blood bursts forth from time to time; and when this happens, it is best to cut the vessel completely across, which will enable its ends to retract and contract, and thus promote the process of nature in closing them. In three or four days the wound is generally healed, but occasionally an aneurism follows; an interesting memoir on which subject has been published by M. Desruelles. (See *Mém. de la Soc. Méd. d'Emulation*, t. ix. p. 277.) In one instance, Cavallini effected a cure by dividing the vessel and compression. (*Collez di Casi Chir.* t. ii. Firenze, 1762.) Sir Benjamin Brodie informed me of a case which he treated successfully in a similar manner. In the course of the present year, 1836, a woman was under my care in University College Hospital for a temporal aneurism, which followed cupping on the temple. As the blood found its way freely into the tumor, after one branch had been tied, I divided another, and applied a compress; the plan was then effectual. Sir Astley Cooper informed me of a temporal aneurism which was produced by a person falling with his temple against the corner of a table.

M. Blandin had a patient, who, in consequence of arteriotomy, suffered acute pains, which extended to the top of the head, in the track of the superficial temporal nerve; this consequence, which is uncommon, may be relieved by lengthening the puncture, or incision, at each of its angles, or even cutting out a portion of the nerve. (See *Dict. de Méd. et de Chir. Pratiques*, t. xiv. p. 422.)

ARTERITIS. *Inflammation of an Artery.* As the coats of arteries possess vessels and nerves of their own, and have an organisation more or less similar to that of all the living textures of the body, they must be liable to inflammation, suppuration, ulceration and gangrene, as well as other morbid changes, especially a deposit of calcareous or atheromatous matter, between the inner and middle coats. Arteritis, as contrasted with phlebitis, or inflammation of veins, is much less perfectly understood, so far as the symptoms and diagnosis are concerned. It is very certain, however, that the arteries are not so irritable as the veins, and, consequently, that arteritis is less frequent than phlebitis. Pathologists divide it into *acute* and *chronic*. The anatomical characters of the acute are, redness of the internal membrane of the artery affected, an effusion of plastic fibrine on its inner surface, thickening of its substance, and sometimes ulceration. When inflammation runs from a wound, or some other point of irritation, along the internal coat of an artery far towards the heart, it is like phlebitis; a formidable disease, rapidly producing great irritative fever, an extremely quick pulse, complete collapse, low delirium, and generally

death. Arteritis, by completely obstructing a main artery and its principal branches, is sometimes a cause of mortification. The treatment of acute arteritis consists in bleeding, purgatives, diaphoretics, low diet, cooling diluent drinks, and perfect tranquillity. Digitalis, tartrate of antimony, and super acetate of lead, are also prescribed on the principle of calming the circulation; but, as Dr. Hope observes, they must be used with discretion. (See *Cyclop. of Pract. Med.* part. ii. p. 149.) After the first violence of the inflammation has been checked, mercury is sometimes given, so as to excite gentle but quick salivation.

Chronic arteritis is more common than acute. The internal membrane becomes thickened, softened, and of a deep, dirty red colour. "These appearances," says Dr. Hope, "are not uniformly diffused, but more marked in the vicinity of calcareous and other degenerations. Hence, some have supposed that these degenerations were the cause of the inflammation. There can be little doubt that they tend, in many instances, to keep it up; but, it is highly probable that the degenerations themselves were originally caused by increased vascular actions of a chronic nature." (See *Cyclop. of Pract. Med.* part ii. p. 145.)—The formation of spontaneous aneurisms is now commonly believed to have its origin in chronic arteritis.

[As our opinions change with regard to the vascular supply to, and mode of nutrition of, any tissue, so must our views, with respect to the morbid changes to which such tissue is liable, and their mode of production, undergo modification. Many histologists now consider that the internal and middle fibrous coats of arteries belong to the so-called non vascular tissues, and that they are dependent for their nutrition not upon the blood carried to them by the vasa vasorum, but that they obtain it by imbibition from the blood current they contain, and with which they are in contact. Pathologists who hold these anatomical views, must explain the well-known morbid conditions of the inner and middle coats of arteries very differently from their predecessors. Accordingly, we find Rokitansky and others ascribing to arteritis only those changes which are observed as the result of inflammation carried on in the outer coat of an artery by the vasa vasorum, to which coat alone they admit these vessels to belong. These morbid changes consist of the ordinary results of inflammatory action, and are attended by the usual symptoms associated with this process, such as increased vascularity, pain, and tumefaction, and are of course accompanied by the ordinary infiltration of serum, lymph, or pus; these infiltrations, it is admitted, may permeate, and more or less disintegrate the middle fibrous coat, and thus secondarily interfere with its nutrition, and even with that of the internal coat. The principal changes produced by inflammation of an artery carried on by the vasa vasorum of the outer coat, Rokitansky thus describes:—1. "*Injection, redness of the cellular sheath of the vessel.*"—This is commonly no longer distinctly apparent after the establishment of those products which we are about to name.—2. "*Infiltration of the cellular sheath*, with a serous, serofibrinous, partially solidifying moisture, causing puffiness; in some few cases the tissue exhibits purulent exudations, which are either diffused, or limited to individual points, or grouped into cir-

cumscribed foci.—3. *Extreme lacerability* — the facility with which the cellular sheath may be removed from the circular fibrous coat. — 4. The circular fibrous coat appears loosened and succulent; admits readily of being drawn into fibres, and separated from the elastic coat; is commonly blanched, and sometimes coloured in different shades of red from the inner surface of the vessel through imbibition, although without any apparent injection. The lining membrane of the vessel is loosened, and may be easily detached or torn; its free surface is dull, and occasionally exhibits a felt-like or wrinkled appearance; it is either pale or reddened by imbibition. — 5. The vessel is frequently, although not always perceptibly, dilated; which is owing to the paralysis of the elastic layer of the cellular sheath and the circular fibrous coat. A coagulum of blood, acting as a plug, is lodged in the canal of the vessel, whose bore is thus more or less completely filled and obstructed. — 6. The presence of a free product (exudation) covering the inner surface of the vessel in the form of a pseudo membrane is, in most cases, problematical.—7. In rare cases arteritis gives rise to a partially or wholly purulent exudation.” (Rokitansky’s *Manual of Pathological Anatomy*, translated by Dr. Day for the Sydenham Society, vol. iv. p. 254.)—It is to the above affections of the arteries that the antiphlogistic treatment is alone applicable.

The remaining, and most frequently observed morbid changes, such as atheromatous, steatomatous, osseous, cretaceous, and fibrinous depositions, Rokitansky attributes to defects and alterations in the mode of nutrition of the internal and middle coats as obtained from the blood itself. Speaking of the atheromatous and osseous deposits so commonly found in the arteries of old persons, he concludes — 1. “The deposit cannot be regarded as the product (exudation) of an inflammation of the arteries. The chronic inflammation of the cellular sheath of the diseased vessel is almost always a secondary consecutive appearance, which associates itself with the already established deposit.—2. The deposit is an endogenous product derived from the blood, and for the most part from the fibrine of the arterial blood.—3. Its formation demonstrates the pre-existence of a peculiar crasis of the blood, which is intrinsically arterial, although at the present time we are wholly ignorant of the character of the peculiarity on which this depends. We must regard the old dogmatic view which sought the cause of the affection in arthritis, as an opinion deficient in proof.—4. In proportion to the extent of the disease of the arteries, so much less likely is it to be combined with tuberculosis; and this disease undoubtedly is in part the cause of that immunity against tuberculosis which we constantly notice in large aneurisms of the trunk of the aorta.—5. The deposit and its metamorphoses present numerous highly important analogies, that have hitherto been wholly neglected. For the sake of brevity, we will here notice only the most important, viz. the deposit also occurring under certain conditions in the veins, the phlebolites, &c.” (Op. cit. p. 272.)

These latter morbid changes, incident for the most part to that advanced period of life in which the nutrition of the body becomes impaired, manifest no recognisable symptoms until the arterial tubes are damaged to an extent to interfere with their mechanical and vital functions of con-

taining and conveying the arterial blood, and when it is probably too late to effect much beneficial change either in the crasis of the blood itself, or in the altered nutrition of the inner and middle coats of the arteries as derived from the blood.

Little more can be done in the treatment of these altered states of nutrition, either in a curative or preventive point of view, beyond regulating and attending to the quantity and quality of the blood circulating in the vessels. It appears probable that a mild, unstimulating diet, so regulated as to obviate habitual repletion during adult life, might retard, if it could not entirely prevent the occurrence of these inevitable changes of structure, which sooner or later invade and deteriorate the tissues of our vital organs.]

ASCITES (ἄσκιτις from ἀσκή, a bottle). *Abdominal Dropsy*, especially that which consists of an effusion of serous fluid in the cavity of the peritoneum. (See PARACENTESIS ABDOMINIS.)

ASPHYXIA (from α privative of, and σφύξη, the pulse). Cessation of the action of the heart from the interruption of respiration, or rather of the effect produced by that function on the blood.

Asphyxia may also be defined to be a suspension of the phenomena of respiration, occurring primarily, and followed by that of all the other functions, and frequently by death.

[The term asphyxia, which signifies literally want of pulse, is objectionable, and likely to lead to erroneous views of the nature of the condition which it is employed to denote. That condition, from whatever cause it may arise, results from the non-arterialisation of venous blood, and the cessation of the pulse only takes place as a consequence of the interruption of the function of respiration. The action of the heart, instead of being primarily affected, is in reality the last of the vital functions which gives way. The incorrectness of this designation has been strongly insisted upon by Dr. Watson, who adopts the term *apnœa*, or privation of breath, as more justly expressive of the condition to which the term asphyxia is commonly given by authors. (See *Lectures on Practice of Physic*, vol. i. p. 61.) The word asphyxia, however, has been so generally in use, that it appears necessary still to retain it; but it should be understood that it is used in an arbitrary sense, and without reference to its etymological signification.]

The general causes of asphyxia may be arranged under three principal heads. 1. Asphyxia from deficiency of air. 2. From the air being unfit for respiration, yet not producing any deleterious effect on the economy. 3. From the inspiration of some gas which is deleterious. As M. Duvergie rightly observes, however, the suspension of functions, or the mode of death in the last case, is very different from what is exemplified in the two first; because it is, in fact, a kind of poisoning, brought about by the action of a deleterious principle, either on the nervous system, or the blood, and the individual may perish, though he is actually respiring air. (Duvergie, in *Dict. de Méd. et de Chir. Prat. art. Asphyxie*.)

Cases of Asphyxia admit of a classification, first, into those in which there is primarily a stoppage of the mechanical phenomena of respiration; and, secondly, into others in which the chemical phenomena are primarily interrupted.

As examples of the first mode of asphyxia may be mentioned those cases in which the muscles of
